The Rorschach Test is said to be appropriate for the assessment of individuals age five years old through adulthood. The assessment may be used alone or in conjunction with other tests. It is described as flexible in its utility, as the results from the Rorschach may provide insight into the examinee's coping styles, tolerance levels, affective presentation, emotional regulation capacities, problem-solving styles, the presence of psychosis, reality testing, and perceptual accuracy. The results of the Rorschach Test could also provide insight into examinees' personal issues (i.e. preoccupations, etc.). Owing to the test's flexibility and the many potential insights its results may reveal, the Rorschach may be useful in a therapeutic environment as one part of a differential diagnosis assessment, to determine how an examinee responds to ambiguity, to determine an examinee's preferred methods of clinical interventions, or to monitor therapeutic progress (Rose et al., 2002).

Administration

Examiners are advised to administer the Rorschach Test in a distraction-free environment. Specifically, an ideal environment to complete the Rorschach Test is in a comfortable and quiet office setting. Within this backdrop, the examiner and examinee should sit at a table next to each other, preferably with the examiner sitting just slightly behind the examinee. The examiner is not to sit face-to-face with the examinee under any circumstances. The purpose of this arrangement is to reduce the potential for cues by the examiner or to influence the examinee's responses or actions during the testing procedures. Examiners should plan to allow at least 90 minutes for the completion of the Rorschach with adults. Approximately 45 minutes is proscribed for the completion of the test with children (Burstein & Loucks, 1989; Rose et al., 2002).

The primary instrument involved in the administration of the Rorschach Test is a set of 10 official cards, as designed by Hermann Rorschach. These cards are 18×24 centimeters. Each card contains an inkblot presented on a white background. Each card's blot has near bilateral symmetry. As proscribed by Rorschach, five of the cards consist of blots printed in black ink. Two of the cards have blots made up of black and red ink. The final three cards contain multicolored inkblots. The cards are placed in numerical order and presented face down in front of the examinee. The first card is placed on top (Burstein & Loucks, 1989; Rose et al., 2002,).

As with all assessment procedures, the establishment of rapport is critical. It is important for the examiner to facilitate an environment in which examinees feel comfortable with the examiner so that they will provide complete and honest responses to each of the stimuli. It

is recommended that the examiner provide an overview of the Rorschach and then address any questions examinees have regarding the test. Examiners should be polite and thorough in their responses without engaging in excessive pleasantries. Once a positive rapport is established, the administration of the Rorschach includes two official stages: the *response* phase (also sometimes referred to as the association stage) and the *inquiry* stage (Rose et al., 2002).

During the *response* phase, the examiner hands each card to the examinee one at a time in the prescribed sequence. The examinee is prompted to answer the question, "What might this be?" The examinee is to respond to this exercise using free association. The examiner records each response verbatim. The examiner may ask the examinee to slow down or repeat comments, as necessary. Exner developed a standardized group of common abbreviations for recording responses, which is used across examiners to simplify this process. Responses are documented on a piece of paper measuring 8 × 11 inches. Each paper should be split into four columns: The first describes the card number, the second the response number, the third column reflects the verbatim response answer, and the fourth column is used for the inquiry stage. It is typical for examinees to provide more than one response for each card. The examiner is to intervene and move on to the next card, if five responses are provided for a particular card. If the examination yields less than 14 responses across all 10 cards, the examiner is to present the cards to the examinee a second time. Whilst documenting the examinee's actual responses, the examiner simultaneously notes behavioral cues as well (Burstein & Loucks, 1989; Rose et al., 2002)

Throughout the Inquiry Phase, the primary goal is to access additional information to confirm that the coding of each response is accurate. Similar in format to the previous stage, the examiner once again presents each card, one at a time, in a proscribed sequence and asks the examinee to further describe what he or she saw in the previous round. The examinee is tasked with showing the examiner what he or she saw, where he or she saw it, etc. The examiner is only to ask clarifying questions during this round of assessment. As the examinee describes the stimuli noted, the examiner notes that which is explained on a verbatim basis and also makes note of the examinee's behavior, such as how the examinee holds the card or rotates it, whether or not the examinee asks permission to rotate the card, etc. The purpose of this phase is to assess perspective while simultaneously assessing for motivation patterns and response tendencies (Rose et al., 2001).

Scoring

Scoring the Rorschach is a complex process and thus requires much training and familiarity with the test (Burstein & Loucks, 1989). The Exner Scoring system (also known as the Rorschach Comprehensive System) is the standard modality for scoring and interpreting Rorschach results (Exner, 1993; Rose et al., 2002). The scoring process involves two major stages: First, all of the qualitative data (i.e. the descriptions provided by the examinee) must be transformed into numerical data. Next, the numeric data is evaluated for use in the structural summary and interpretation (Exner, 1993).

Exner (1993) explained that the purpose of assessing an individual via the Rorschach and scoring those results is to provide a holistic picture of that individual. As such, the

examiner must maintain a global perspective, considering the various interrelationships affecting that person's personality, rather than zeroing in on one particular coded variable. Given the need to assess the entire person, data is not coded until after the inquiry stage of the assessment. Since these stages are sometimes completed at separate times, it is important to note that the examinee's experiences may vary between stages. The examiner is also tasked with attending to and coding ALL of the data elicited from the interview. The failure to assess all responses, in full, may lead to a distorted understanding of the examinee's personality.

Given the extensive empirical research supporting its utility, Exner's (1993) *Comprehensive System* is typically applied during the scoring process. His book by the same name provides specific and explicit instruction regarding how to code the qualitative data into numerical data (Exner, 1993). Within this scoring framework, each examinee's response to each ink-blot must be coded under multiple categories. These categories include:

- Location and Developmental Quality: Where on the card the examinee noted the stimuli and the degree of meaningful organization used within the response;
- Determinants: The characteristics of the inkblot to which the examine responded;
- Form Level: The degree to which the examinee's description of a form fits the area of the inkblot reviewed;
- Contents: The name or class of objects used in the response out of 27 prescribed possible categories;
- Popularity/Originality of Responses: How well the examinee's response aligns with the most popularly given responses;
- Organizational Activity: The degree of organization leveraged to integrate the contents described in the response, and
- Special Scores: Any unusual deviations that must be noted (i.e. developmental disability, etc.).

<div align="right">(Burstein & Loucks, 1989; Exner, 1993; Rose et al., 2002).</div>

The process of coding in each of these categories involves a number of unique considerations and entails the use of unique symbols. A complete explanation of the same is available via Exner's *Comprehensive Summary (*Exner 1994, 1995*)*.

Results

Once scoring is completed, the scores are transferred to the "Sequence of Scores" sheet. This sheet is composed of 10 columns listing all of the coding scores for each response. The columns included on this sheet include:

1) Card
2) Response No.
3) Location and DQ
4) Location No.
5) Determinants
6) Form Quality
7) Content(s)

  8) Pop
  9) Z-Score
10) Special Scores

Appropriate and corresponding codes are included in each of these columns for each inkblot card. The examiner then completes a series of calculations to determine a structural summary of the assessment data. Combined, the information presented in this scoring process provides the examiner with an overview of the examinee's personality (Burstein & Loucks, 1989; Exner, 1993; Rose et al., 2002). As with the basic scoring processes, a more detailed explanation of the coding and calculation process is included on the Sequence of Scores sheet, available via Exner's (1993) *Comprehensive System*. It should also be noted that there are now a number of software programs, including RIAP and ROR-SCAN, which help simplify this process for those who do not want to complete it by hand (Rose et al., 2002).

Interpretation

Interpretation of the Rorschach may begin as soon as the data is organized into the structural summary. The interpretation process consists of two stages: The Propositional Stage and the Integration Stage. As with scoring procedures, effective interpretation of the Rorschach Test relies on the extensive training, experience, and demonstrated competence of the examiner. Within the Propositional Stage, the examinee's scores are compared and contrasted with established norms among clinical and non-clinical populations. Based on these comparisons, the examiner formulates hypotheses regarding the examinee's personality. The examiner is advised to be conscientious regarding the degree to which the demographics of the norms correspond with those of the examinee (Burstein & Loucks, 1989; Exner, 1993, 1994, 1998; Rose et al., 2002; Weinter, 1998).

During the Integration Stage, the examiner reviews the examinee's response presentation across seven clusters, including:

1) Information Processing
2) Cognitive Mediation
3) Ideation
4) Capacity for Control and Tolerance for Stress
5) Affect
6) Self-Perception
7) Interpersonal Perception and Relations

Additionally, examiners are to assess for Suicide Constellation (S-Con) as a separate variable (Exner, 1993).

Exner (1993, 1994, 1995) referred to the first three clusters as the "cognitive triad." The overlap between these clusters highlights Exner's assertion that none of the seven clusters ought to be examined in isolation, as they work co-operatively to provide insight into an individual's functioning. Exner (1994, 1995) also suggested that, technically, the clusters may be assessed in any order, yet most examiners tend to review them in the order suggested either by the referral question or per Exner's identified Key Variables, which are explained in detail within the *Comprehensive System* (1993). Based on the analysis across clusters and validity indicators, the examiner will develop a series of hypotheses addressing

the cognitive emotional and interpersonal variables affecting the examinee's presentation. The examiner combines this data and integrates it into a meaningful description of the examinee's relevant personality variables. The conclusions are then typically incorporated into a larger assessment process, which likely includes a clinical interview, a review of the examinee's life history, and an examination of collateral resources, and other psychological examinations (Rose et al., 2002).

Strengths and Weaknesses

The use of the Rorschach Test has long been controversial due to critiques regarding its perceived reliability, validity, and utility within a clinical environment (Cronbach, 1949; Garb, 1999; Meehl, 1959; Meyer, 1997). A main point of concern for opponents of the Rorschach test is the fact that the instrument is no longer used as originally intended. They argue that Hermann Rorschach wanted the test to serve as a diagnostic tool rather than one that assesses personality in general. As such, this causes some concern for the Rorschach Test's face validity (Garb, 1999; Weiner, 1997). Supporters of the test argue that while Rorschach might have wanted the instrument to offer insight into psychopathology, the instrument is ultimately sufficiently developed to offer insight into personality outside dysfunctional circumstances. In fact, many proponents of the instrument argue that its refinement, which is based historically on several traditions of psychology, may actually now serve as a more robust tool than Hermann Rorschach could ever have imagined.

Another concern that opponents of the Rorschach Test typically identify is its scoring. Over the years, several different scoring systems have been applied to the Rorschach Test, each focusing on a different objective (Klopfler, 1946; Piotrowski, 1957; Rapaport, Gill, & Schafer, 1945). This concern is valid, but has been addressed extensively by Exner and his colleagues (1991). Via the development of the Comprehensive System, Exner and his colleagues (1993) standardized the administration and scoring of the Rorschach Test. The use of the Comprehensive System is now supported by a large body of empirical research, which includes a sizable normative sample, including information across several reference groups, which seems in line with the spirit of Rorschach's original work (Weiner, 1997). Numerous studies have also been completed over the past several decades that cross-validate the research regarding the identified normative groups as well, further supporting the test's utility in terms of better understanding personality (Exner, 1991). Opponents of the test caution, however, that there is minimal research regarding the use of the Rorschach with minority populations (DeVos & Boyer, 1989). Therefore, it is unknown how helpful this instrument may be in assessing members of those groups. Research also suggests that the Rorschach Test is limited in the extent to which it might provide examiners with the ability to understand an individual's presentation. For example, the literature indicates that the Rorschach Test is unable to assess memory, intelligence quotient, neuropsychological impairment, learning disabilities, daily living skills, or violence potential well (Meyer, 1999). As such, it is incumbent on the examiner to assess these facets separate from the Rorschach Test.

Collectively, the literature critiquing the Rorschach Test highlights the fact that this instrument is a highly complex tool, which requires extensive training to properly administer, score, and interpret it. The ambiguity of the test requires the examiner to be

incredibly skilled in test administration and interpretation, as well as familiar with the structure of personality and complexities of psychopathology. This instrument is best utilized in conjunction with other instruments to gain a comprehensive overview of personality. Within a constellation of instruments, the Rorschach is probably best equipped to provide insight regarding the examinee's worldview and object-representations as well as their perceptual accuracy and reality testing.

Tell-Me-A-Story (TEMAS)

Celeste M. Malone, Amber Gibson, and De'Lon Isom

Howard University

The Tell-Me-a-Story (TEMAS; Constantino, Malgady, & Rogler, 1988) is a multicultural thematic apperception test designed for use with racial/ethnic minority and non-minority children and adolescents aged 5 to 18. The TEMAS was developed specifically for culturally and linguistically diverse children and adolescents. The TEMAS differs from other apperception tests such as the Thematic Apperception Test (TAT) in that the stimulus cards are printed in color and were designed to depict everyday situations. There are two sets of parallel cards: one for Latino and Black children and one for White children. Additional versions of the TEMAS stimulus cards have been developed for Argentinian and Orthodox Jewish children (Constantino et al., 2014) and Asian American children (Constantino & Malgady, 2000). The 23 TEMAS stimulus cards depict urban surroundings with the following themes: home and family, peer interactions, street experiences, school and fantasy, and day dreaming. In addition to the two versions, the TEMAS can be administered using a short form administration of nine cards and the long form administration using all 23 cards.

The TEMAS was standardized on a sample of 642 children (281 male and 361 female) attending public schools in New York. Although the test can be administered to examinees up to age 18, norms are only available for examinees ages 5 to 13. The norms are based on the assumption that the examinee is a typically developing child without serious sensory or intellectual impairment. There are four normative tables: White, Black, Puerto Rican, and Other Hispanic. While the TEMAS has an ethnically diverse sample, there are criticisms of the small and geographic restrictive normative sample (Flanagan & DiGiuseppe, 1999).

The examiner presents the stimulus card to the examinee with the directions of telling a story. In the TEMAS stories, examinees must include information about the characters and their relationship, what they are doing before and after the conflict depicted on the stimulus card, and what the main character is thinking and feeling. The stories are scored along three dimensions (cognitive, personality, and affective) according to standardized scoring procedures. The three dimensions are cognitive functions, personality functions, and affective functions. The 18 cognitive functions refer to how the examinee organizes information about self, the environment, and the relationship between the two when telling a story

about the picture. The nine personality functions are scored on a 4-point scale, ranging from "very maladaptive" to "mature and responsible." Each stimulus card is designed to pull for at least one personality function. The personality functions are: Interpersonal Relations, Aggression, Anxiety/Depression, Achievement, Delay of Gratification, Self-Concept of Competence, Sexual Identity, Moral Judgment, and Reality Testing. The affective functions refer to the affect or mood states attributed by the examinee to the main character in the story. The affective functions are scored on the affect of the main character and the congruence of the reported affect with the story's content. The seven affective functions are Happy, Sad, Angry, Fearful, Neutral, Ambivalent, and Inappropriate Affect.

Follow-up studies of the TEMAS demonstrated that the profiles of the TEMAS personality function can discriminate between clinical and non-clinical samples (Flanagan & DiGiuseppe, 1999). In a study of Black and Hispanic children, the TEMAS discriminated between public school children and children diagnosed with DSM-III mental disorders. The primary discriminating personality functions were Person Relations, Aggression, and Anxiety. To a lesser extent, Sexual Identity, Moral Judgment, and Reality Testing also discriminated between the two groups (Constantino, Malgady, Rogler, & Tsui, 1988). Similarly, in a study to establish evidence of the non-minority version of the TEMAS, the personality functions of Interpersonal Relationships, Aggressiveness, Anxiety, Achievement Motivation, and Self-Concept discriminated between White public school children and White children in mental health facilities (Constantino, Malgady, Colon-Malgady, & Bailey, 1992).

Studies in which children were assessed with both the TEMAS and the Behavior Assessment System for Children (BASC) showed significant correlations between TEMAS personality functions and BASC components. This may suggest that the TEMAS and BASC may assess different aspects of functioning and may be complementary measures. Specifically, the personality function of Reality Testing significantly correlated with the BASC clinical maladjustment composite, emotional symptoms index, school maladjustment composite, and sense of inadequacy. As such, the TEMAS Reality Testing may be an overall index of poor adjustment (Flanagan, 1999).

Thematic Apperception Test

Gerald E. Nissley and Elvis DeFreese

East Texas Baptist University

The Thematic Apperception Test (TAT) is a projective instrument used by clinicians to get psychodynamic understanding of personality features through administration of ambiguous cards to which examinees respond with narratives. While some have historically hailed projective testing as a "mental X-ray," the TAT and other such tests have become highly controversial. The TAT relies upon the projective hypothesis, which suggests that the examinee's responses reflect important facets of their personality. Although the TAT has been found useful for bolstering assessments of personality as a widely used tool, some questions have been raised regarding its validity and reliability. Recent trends in research have focused on standardizing scoring for interpretation and further defining the purposes for which the TAT can offer illumination of personality.

Test History and Development

Christina Morgan and Henry Murray of the Harvard Psychological Clinic originally proposed the TAT's rationale and protocol in 1935, but the test was further elaborated upon in more formal 20-card formats in 1938 and 1943. Murray's rationale for the test included two goals. First, he suggested that the TAT would allow psychodynamic clinicians to glean important psychic material from clients that they were either unwilling to share or were unaware of. Second, he suggested that use of the instrument would allow clinicians to work more efficiently. This second proposed advantage was particularly important, as psychoanalysis was already being challenged by more efficient behavioral models that reduced the length of treatment significantly. Since its development, the TAT has remained incredibly popular with clinicians as the second most used projective instrument. It has also inspired additional projective assessments, such as the Children's Apperception Test, Tell-Me-A-Story (TEMAS), and South Mississippi TAT as responses to the perceived limits of the instrument.

Initially, the theory behind the TAT was primarily Murray's need-press model. However, as the test gained in notoriety, others found the TAT effective for assessing dynamics consistent with conventional psychodynamics, objective relations, and narrative theory. In Murray's model, personality is largely conceptualized through the interaction of internalized needs and values with the contextualized external world. The ambiguity of the cards used in the TAT seemingly provide a window into the expression and intensity of these themes as experienced by the individual. Psychodynamic researchers have suggested that the TAT also could be used to assess superego conflicts, castration anxiety, perception of parental figures, drives, and defense mechanisms. Object relations theorists indicated that the TAT could be used consistently as well to assess objects that are internalized, moral integrity, affective investment, and social motivation. All of the theorists suggested that the TAT is effective at assessment based on the projective hypothesis, which indicates that the ego projects unconscious content onto the ambiguous cards in the absence of guidance on how to filter responses in a socially appropriate manner.

Administration, Scoring, and Interpretation

Murray suggested that an emphasis upon rapport-building was central in establishing the assessment environment for the TAT; thus, he suggested an interpersonal office setting where the cards of the TAT could be administered and the examiner could personally receive the verbal responses of the examinee. In his original protocol, Murray indicated that the examiner should sit so that he or she was not in the direct visual field of the examinee to avoid impacting responses. The TAT consists of 20 cards on which black-and-white pictures are printed. The cards can be administered to adults and children. Murray originally recommended administering all 20 cards to each examinee, but protocols with fewer probes have flourished. In selecting fewer cards, protocols have developed in which certain cards are used for specific personality and diagnostic concerns. Upon administration, examinees are read a standardized introduction to the test, and they are instructed to develop stories for each card that have a beginning, a middle, and an end. Additionally, examinees are directed to include the thoughts and feelings of characters in their stories. During administration, the examiner records verbatim – with notes of pauses, stuttering, and other observations – the narratives shared for each card. The examiner is required to ask for clarification if required components of stories are omitted, and inquiry consistent with other projective tests can be undertaken after administration of all cards for additional information.

Regarding scoring, Murray originally suggested the needs and presses should be listed out from the responses of the examinee and subsequently weighted. Others have used thematic interpretations of the narratives, and still others have focused on scoring models consistent with theories of object relations and conventional psychodynamics. However, the most recent advances in scoring and interpretation have occurred in terms of standardized scoring. Bellak (1997) developed an approach that relies on quantifiable ratings that weight information from both individual stories and themes that develop across stories. Bellak's approach focuses on scoring along primary drives and needs of the hero, conceptualization of the external world, relationships to others, conflicts, anxieties, defense

mechanisms, superego dynamics, and ego strength and integrity. In comparison to other projective tests, the TAT provides some of the least ambiguous stimuli and requires the most comprehensive responses of the examinee. Despite this, standardized scoring has lagged behind Exner's approach to the Rorschach and other scoring protocols for projective drawings.

Once scored, TAT data can be used to define personality constructs of the examinee. In Bellak's system of interpretation, the scoring yields conclusions that are descriptive, interpretive, and diagnostic. Such levels of interpretation yield findings that not only provide themes of experience and context of the patient but yield insights into attributes and underlying schemas of the examinee that predict and explain his or her presentation. Additionally, interpretation also tends to include assertions regarding intelligence and maturity. Regarding interpretive context, it is also important to consider if the stories developed were cliché or previously heard narratives. A high concentration of such responses might be suggestive of ego defensiveness.

Psychometric Properties

In consideration of psychometric properties, challenges exist for assessment. For example, clinicians often use different selections of cards and rely upon intuitive theme-based approaches to scoring and interpretation that do not lend themselves to rigorous evaluation. However, the evaluation of standardized scoring systems suggests some evidence of psychometric confidence. For example, test-retest reliability was found to be good across various scoring systems (.85 or higher for most of them). However, given that many clinicians do not use the test the way it was assessed in such studies, one might wonder if these reliability coefficients are generalizable. While the scoring systems show strong test-retest reliability, given that examinees tend to tell different stories in response to the same card if presented at a later time, the test-retest reliability of the actual test is dubious. Additionally, internal consistency cannot be evaluated, as each card measures an independent factor of personality.

While reliability of the TAT when standardized scoring systems are employed is generally good, the evidence regarding validity is much more mixed. On one hand, the TAT does not measure intensity of a construct; thus, a high score on anxiety does not equate to frequent expression of anxiety by the examinee. On the other hand, research on criterion-related validity in relation to need for achievement, affiliation, and power has shown positive results. Additionally, research has shown the TAT can be used to accurately diagnose and make inferences in clinical settings. With regard to construct validity, some research has shown that narratives provided in response to certain cards are likely to correlate to specific personality dynamics. For example, examinees who respond with a story of jumping from a window in response to a card with a silhouette of an individual in a window tend to experience some suicidal ideation.

The TAT has been used in research and practice across the world, and versions of the test have been developed for specific cultural groups, including Hispanics, African Americans, and Chinese. These culturally fair versions have typically involved the development of different cards that are socio-culturally relevant; however, this process has often not included additional development of culturally appropriate norms and scoring systems.

The Tell-Me-A-Story and Roberts-2 – two alternatives to the TAT – are exceptions to the latter observation.

Despite some questions of psychometric properties, the TAT remains among the most popular tools for clinical and research-related assessment of personality. Reasons for its popularity tend to relate to its utility. Examiners perceive they can gain insights into covert aspects of an examinee's psyche because the test discourages faking and is interesting to examinees. Furthermore, the test assesses personality broadly, as opposed to factor-based objective personality tests.

Trends and Future Directions

Although the TAT remains popular, it has become less used in recent years. Reasons for the decrease in popularity include managed care's emphasis upon cost-effective instruments. The TAT requires significant time to administer, score, and interpret; in contrast, there are now many other tools that can collect similar information in less time. Moreover, as clinicians are required to be competent in an ever-increasing number of tests, less time is available for the considerable training necessary for effective utilization of projective tests. While the longstanding questions regarding the TAT's psychometrics have not historically diminished its popularity, more recent research calling into question its validity and reliability likely adds controversy that will contribute as the previously mentioned concerns diminish popularity. Ironically, even as the limits of the test have promoted significant research into scoring systems and alternative tests, the consequence of these processes include less utilization of the TAT itself.

The TAT's popularity is threatened by a variety of variables, but a number of advances have occurred in research that suggest areas for further development. Most notably, scoring systems continue to be produced, and these systems tend to be increasing validity and reliability evidence necessary for clinicians to use the tool with confidence. A number of object relations researchers have developed scoring systems that show promise for using the TAT for assessing introjects and defense mechanisms. Additionally, Weston's scoring system has been shown to use the TAT in a valid and reliable manner for diagnosis of personality disorders. Moreover, there has been increased interest in using the TAT to assess affiliation, achievement, and power; in turn, research has been developing evidence of the TAT's validity for assessing these characteristics in cross-cultural contexts. If the further development of efficient scoring systems with strong psychometric properties can be paired with technology that speeds up administration, the TAT may be able to transition into the next era of personality assessment for the reasons above that promote its popularity.

Word-Related and Figure-Construction Projection Techniques

Lucas M. Sohn, Jennifer N. Yuen, and Jessica L. Borelli

University of California, Irvine

Projection techniques use responses to semi-structured stimuli to infer aspects of personality. These techniques are guided by the assumption that, compared to self-report measures and structured behavioral tasks, their unstructured or ambiguous nature offers participants more opportunities to reveal aspects of their personality (see Rorschach Test). The underlying premise – that responses to ambiguous stimuli reveal aspects of personality – has been challenged for decades (e.g. Murstein, 1961).

As such, scholars suggest that interpretations drawn from projection tasks should remain exploratory. When interpreting responses, researchers should balance two dialectic principles: that every detail of a participant's response may carry meaning, and that hypotheses, however plausible, should remain conjecture until corroborated by more objective sources of data (see Tharinger & Stark, 1990). In what follows, we review word-related and figure-construction projection techniques.

Word Association Tests

With word association tests, participants respond to stimuli (words) by saying the first thing that comes to their mind. Differences in participants' responses are thought to reflect aspects of their personality. For instance, participants may be shown a card with the word "mouth" printed on it. A response of "talk" may be hypothesized to reflect an interpersonal orientation.

While the structure of these tests has changed little since early examinations of word associations, researchers have modified stimuli used in attempts to make them more evocative and standardized. Rules for interpretation differ by iteration of the assessment tools, but most scoring systems for word association tests involve evaluation of the content of responses, response time, and uniqueness of response.

Sentence Completion Tests

Sentence completion tests expand upon word association tests by adding structure; instead of responding to a single word, participants complete sentence stems. Compared to word association tests, sentence completion tests tend to be more focused in scope and interpretation and have stronger empirical support. Sentence completion tests are typically scored by examining response content. For example, a response to "I FEEL LIKE" of "I am drowning in grief" might suggest poor psychological adjustment. Interpretations are judged by their plausible relevance to a given construct. As is the case for most projection tests, confidence in interpretations is bolstered by the presence of corroborating information.

The Washington University Sentence Completion Test (WUSCT)

The WUSCT is used to identify the level of ego development that best characterizes an individual along Loevinger's Theory of Development (Hy & Loevinger, 1996). This theory posits that there are eight stages of personality growth, with maturation defined by an individual's progression in their perception of and response to his/her social environment.

In the WUSCT, sentences (*N*=36) are scored individually and participants are given an overall score. The recommended procedure for determining the overall score involves considering item scores, their distribution, and accounting for outliers. Studies of the WUSCT suggest it may be a psychometrically sound measure of ego development (e.g. Westenberg, Hauser, & Cohn, 2004). Recently, lower scores on the WUSCT have been shown to be positively correlated with internalizing symptoms and negatively correlated with aggression and substance abuse (Duffy, Ruegger, Tiegreen, & Kurtz, 2017).

Rotter Incomplete Sentence Blank (RISB)

The RISB is a sentence completion test designed to screen for difficulties in psychological adjustment (Rotter & Willerman, 1947). In the RISB, participants complete 40 sentence stems. Coders rate responses to each item on a scale of 0 to 6, where low scores indicate positive adjustment and high scores indicate conflict. With a possible range of scores from 0 to 240, scores over 144 suggest cause for clinical concern.

The RISB can be used as a measure of psychological adjustment: responses to the RISB distinguish between people receiving treatment for emotional or behavioral problems and those from a community sample with accuracy ranging from 75–80% (Lah, 1989), which provides evidence of its predictive validity. Moreover, high scores on the RISB have shown an association with anxiety, depression, and interpersonal difficulties (Torstrick, McDermut, Gokberk, Bivona, & Walton, 2015). However, because more precise tests exist, researchers suggest that the value of the RISB lies in its ability to generate hypotheses about an individual's personality, rather than diagnosis.

Figure-Drawing Tests

Figure-drawing tests ask participants to draw human figures, trees, and/or houses. Tests often include an inquiry procedure, wherein participants are asked about the drawings they produce (e.g. "How does this person feel?"). However, no standardized inquiry procedure

exists. The content of a participant's drawings, the manner in which a participant approaches the task, and what a participant says during the inquiry can yield insight into his/her perceptions of the self, others, or family. For example, if a participant describes her drawing as "standing up straight and tall," a researcher may hypothesize that the participant perceives herself in this way.

Draw-A-Person (DAP) Test

On the DAP test, participants are asked to draw a person. Next, participants are asked to draw a person of the opposite gender. This procedure can be supplemented by asking participants to draw a self-portrait. Last, participants respond to an inquiry about their drawings; e.g. "Please tell a story about this person." Interpretations of DAP responses have become more conservative over time: while the measure's creator initially argued that singular aspects of drawings could reveal broad personality characteristics (Machover, 1949), researchers now caution against making such conclusions based on a single variable. One factor that may hinder the reliable inference of information from these drawings is the range of meanings a drawing may represent: an ideal version of the self, the perceived version of the self, perceptions of others in general, or specific people in a participant's life. Newer iterations of the DAP test involve systems for arriving at specific conclusions about psychological well-being. Two such systems have received consistent empirical support (Tharinger & Stark, 1990; Naglieri & Pfeiffer, 1992). Recently, scholars have called into question assumptions the DAP test makes about gender and how it should affect interpretation of DAP responses (Picard, 2015).

House-Tree-Person (HTP) Test

On the HTP test, participants draw a house, a tree, and a person, which are interpreted in aggregate. Some researchers include an inquiry as well, asking participants to describe their drawings. The HTP test was designed to assess children's psychological functioning (Buck, 1948). House drawings are thought to reflect how participants perceive their home lives and families, while tree and person drawings are thought to reflect how participants perceive the self. By eliciting a child's thoughts and feelings about his/her family life through house drawings, the HTP test is thought to provide a relatively comprehensive examination of a child's adjustment. Coding systems for the HTP test have received little attention from researchers. Thus, little empirical evidence exists to support the utility of this measure in assessing overall adjustment. However, some success has been reported in using the HTP test as a measure of specific constructs, such as resilience (Roysircar, Colvin, Afolayan, Thompson, & Robertson, 2017).

Draw-A-Person: Screening Procedure for Emotional Disturbance

The DAP:SPED is an atheoretical coding system for the DAP used to assess psychological adjustment (Naglieri et al., 1992). Participant drawings are examined for the presence of 55 items, each of which has been shown to correlate with emotional disturbance in nationally representative samples; for example, "crossed eyes." If a given characteristic is present, a score of 1 is given for that item – if not, a score of 0 is given. Scores for all drawings are

summed and standardized, with higher scores indicating more emotional disturbance. The DAP:SPED has extensive psychometric support in screening for emotional disturbance (e.g. Bardos & Doropoulou, 2014).

Strengths and Limitations

Advocates of projection tests argue that these techniques offer advantages over self-report measures, contending that their unique format enables these assessments to reveal things of which a participant is not aware. In contrast, critics assert that the central assumption underlying this method – that participants project aspects of their personality – is not sufficiently supported by empirical studies. Here, advocates for projection techniques make a distinction between idiographic and nomothetic approaches. The former constitutes the holistic use of projection tests to generate hypotheses about a participant's personality. Owing to the open-ended nature of such hypotheses, it can be difficult to study them systematically. The latter can be characterized as the search for associations between responses and specific aspects of personality. While limited evidence exists for an idiographic approach, empirical studies suggest that word-related and figure-construction techniques can support research endeavors. For example, scholars have concluded that the DAP test can measure treatment progression (Robins, Blatt, & Ford, 1991).

The format of projection tests offers several benefits that self-report measures do not. Performance on projection tests may be harder to fake, given that it can be unclear to participants what constitutes a socially desirable response. This argument is less applicable to sentence completion tests, which are relatively straightforward compared to tests like the HTP. In addition, children, people with limited language skills, and people hesitant to divulge personal information may find these techniques more accessible than interviews or self-report questionnaires. Scholars have also argued that figure-drawing techniques are less culturally bound than other common measures. Last, the materials required for administering word-related and figure-construction projection tests tend to be simpler than those required for many self-report measures and interviews, and the administration time is shorter.

Behavioral Genetics, General Features and Methodological Issues

Amanda ElBassiouny[1] and Shay Luu[2]

[1]*California Lutheran University*
[2]*Howard University*

The purpose of the field of behavioral genetics is to understand the extent to which genetics and the environment affect the variability observed in behaviors. More specifically, behavioral genetics has contributed to the understanding of personality by demonstrating the influence genes and heredity have on its development, along with environmental factors.

Behavioral genetics is designed to identify and differentiate the effects of genetics and the environment on behaviors by examining people of differing degrees of genetic relatedness and assessing the similarities and differences among them (Plomin, 1986). More specifically, in the field of personality psychology, this domain has been employed to expound upon the role of genetics and environmental factors in personality development. Therefore, in using the techniques of behavioral genetics to explore personality traits, a comparison is made between the personality traits measured and the genetic similarity between participants. This would then include comparisons between monozygotic (identical) and dizygotic (fraternal) twins. By measuring personality differences between monozygotic and dizygotic twins, conclusions about genetic influences can be drawn based on genetic similarity. Accordingly, to conclude that genetics is a contributing factor to explaining personality traits, monozygotic twins should be about twice as similar in their personality traits as dizygotic twins, whereas if dizygotic twins' similarity is larger than expected based on genetics, it can be concluded that this can be attributed to a shared environmental experience. Differences observed among monozygotic twins are due to individual differences experienced in their unique environments.

In behavioral genetics, comparisons can be made among adopted and non-adopted siblings to assess the effects of heredity and the environment. When non-adopted siblings are more similar than adopted siblings, this can be attributed to genetics since the former shares 50% genetic similarities whereas the latter have no genetic similarities. However, when adopted siblings who do not share a degree of genetic relatedness have similarities among their personality traits, this is due to the environment that they shared through

their rearing. Therefore, researching personality differences and similarities among family members with varying degrees of genetic relatedness, along with comparing them to adopted, unrelated siblings, allows further explication of the effects of both nature and nurture in understanding personality development.

Advances in the research methodology in behavioral genetics have provided a greater understanding of the influences on the development of personality traits. Studies including large sample sizes of both monozygotic and dizygotic twins reared together have been conducted. Further, studies from both biological and adoptive families of monozygotic and dizygotic twins reared apart have also been examined. Lastly, model fitting has been employed as a powerful statistical technique to analyze the aforementioned methodologies (Bouchard, 1994).

Behavioral genetics takes the approach of quantifying the variances that attribute to phenotypic variations among individuals. This includes measuring heritability (h2), which is commonly referred to as the genetic effect size, and is a measure of the variance in phenotype accounted for by genetics. Variance corresponding to environmental factors is also measured to account for the remaining phenotypic variation. Environmental factors comprise shared environmental variance (c2) and non-shared environmental variance (e2), which consists of environmental influences that are common to the members of a familial unit and those that are only specific to the individual, respectively. Non-shared environmental influences contribute to family members evolving into unique individuals. Examples of these factors can include friendships outside of the family, relationships with teachers and mentors, and differential interaction patterns with parents (Saudino, 2005).

Twin studies have sought to capitalize on the ability of using such participants to assess and quantify the genetic and environmental contributions of personality. Some of the most influential of such studies included 850 pairs of monozygotic and dizygotic twins tested by Loehlin and Nichols and compared to non-twin siblings, the 20-year-long Minnesota Study of Twins Reared Apart (MISTRA) which compared monozygotic twins to a control group of dizygotic twins who were both separated before the age of four years old, and the Minnesota twin registry which included self-report measures of personality traits and individual differences from more than 8,000 twins and their family members. Such twin studies have revealed that the genetic contribution to personality ranges from 42% to 46%. Thus, such studies of monozygotic and dizygotic twins further emphasize and support the importance of genetics in understanding personality.

While behavioral genetics is an advancing field that is aiding in uncovering the biological and environmental underpinnings of human behavior, there are important methodological concerns in the field. Issues of replication in the findings that there are genetic contributions to various psychological phenomenon, including schizophrenia, intelligence, and homosexuality, have led critics to raise the issue of whether genes influencing the development of the aforementioned topics even exist. Perhaps the issues in replication are not because genes are not implicated in such phenomena, but rather, the methods being used need further sophistication to be able to accurately distinguish genetic and environmental factors from each other. For example, when studying both factors concurrently in twins reared together, genetic and environmental contributions may be easily confounded and more sensitive methodological tools may be needed to further tease apart their differential impacts.

Along with methodological concerns, certain ethical issues have arisen surrounding the implication of the role of genetics in psychological phenomena. For example, finding that genetics influences the development of people with antisocial personalities can have a serious impact on how the justice system handles criminals who were destined to be deviant. Consequently, having an understanding of which genes are implicated in such cases of deviance and violence can ultimately lead to genetic testing in utero that can identify embryos displaying such genetic markers. Such practices of eugenics that can stem from the understanding of genetic contributions may also underscore the importance of environment to interact, and even counteract, one's biology. Thus, biology is not necessarily destiny and the environment can still have a major impact in how a person's personality may develop.

The future of behavioral genetics research rests in the field of molecular genetics, which aims to explicitly isolate and identify specific genes associated with personality traits and behaviors. The Human Genome Project, an international endeavor which has sought to identify the chemical base pairs that consist of the human deoxyribonucleic acid and associated genes, has aided in the advancements in molecular genetics research. Further, studies that seek to determine links between genes, which can allow for genetic testing, also help to advance the understanding of genetics' role in personality development. Such linkage analyses elucidate the genes and genetic markers that are likely to be inherited simultaneously because of their chromosomal locations. Thus, having an understanding of the components of humans' genetic maps at the molecular level will allow for future research to more accurately identify the specific gene or interaction of genes that contributes to the development of particular personality traits.

Biochemical Assessment

Josh Root[1], Femina P. Varghese[1], Meryl Jacob[2], and Kate Myers[1]

[1]*University of Central Arkansas*
[2]*University of Texas at Dallas*

Recently, attempts to understand personality have begun to focus on biological underpinnings. Biological mechanisms of personality include brain structures and their corresponding biochemical modulators. Researchers have identified biochemical compounds that excite, inhibit, and modulate brain structures associated with personality dimensions. As science moves toward the psychobiological study of personality, researchers are moving toward developing valid assessments for the presence and level of biochemicals relevant to personality. Biochemical assessment methods are differentiated by factors such as in vivo versus in vitro assessment, invasiveness, sensitivity, and specificity.

A common method for assessing the level of biochemicals is by sampling bodily fluid. Fluids such as saliva, blood, urine, and cerebrospinal fluid (CSF) are accessible sources of hormones and neurotransmitters. These samples vary in the degree of invasiveness. Samples obtained from CSF fluid are highly invasive. Blood samples are slightly less invasive than CSF samples, but are still more invasive than urinary or saliva samples. Samples of bodily fluids can be analyzed with techniques such as biological assessment, immunoassay, and mass spectrometry to provide quantitative data on the biochemicals in the sample. There is a notable limitation to assessment by blood, urine, or CSF sampling when these methods are used to assess personality. Not all neurotransmitters or hormones collected originate in or affect the CNS. Acetylcholine, for example, is the primary neurotransmitter in the neuromuscular junction, which is controlled by the peripheral nervous system.

After a blood, saliva, urine, or CSF sample has been collected, it must be analyzed. One method of analysis is called biological assessment, otherwise known as bioassay. In a bioassay, the sampled molecule is injected into a tissue preparation and then compared to a standardized dose-response curve for that molecule. Tissue preparations can be either in vivo or in vitro. In vivo preparations involve injecting the sample into a live being and

observing the response. With an in vitro preparation, the sample is injected into a tissue or cell separate from a live being. An example of an in vitro preparation would be the assay of endogenous testosterone in a preparation consisting of calf serum and adult mouse testes (Van Damme, Robertson, and Diczfalusy, 1974). The molecules analyzed using bioassay range from neurotransmitters such as acetylcholine, dopamine, and serotonin to hormones like cortisol, testosterone, estrogen, and oxytocin. Investigators have used the bioassay technique to assess the relationship between hormone levels and male or female characteristics of personality in women (Baghaei et al., 2003).

The immunoassay is the current method for identifying analytes, or specific molecules of interest. In an immunoassay, the sample and a specified reagent are injected into a preparation. The reagent, an antibody or antigen, selectively binds to the compound of interest in the sample. Once the reagent attaches to the compound of interest, a chemical or electrical separation method is used to isolate specific compounds. The results of an immunoassay can be used to explain the basis of certain personality traits. For example, researchers have used an immunoassay to analyze cortisol in saliva samples to test the idea that people with psychopathic personality traits exhibit a dampened response to stress (O'Leary, Loney, & Eckel, 2007).

Samples may also be analyzed with high-performance liquid chromatography (HPLC). Liquid chromatography separates the compound of interest from extraneous compounds in the sample. Two phases contribute to the separation of the compounds: the stationary phase and the mobile phase. In the stationary phase, a glass container is filled with an adsorbent material. Materials are selected for the stationary phase based on qualities such as the pH level, particle size, polarity, and organic-inorganic composition; these characteristics influence the degree to which the molecules in the sample are attracted to the stationary phase material. Once the stationary phase has been prepared, the sample is injected. When the sample has been injected into the stationary phase, a solution is pushed through the preparation. Pushing the solution through the adsorbent material is called the mobile phase. Molecules in the sample separate based on the relationship between the molecules in the sample, the stationary phase, and the mobile phase. For instance, a molecule that shows a higher affinity for the mobile phase will move farther in the tube than will molecules with a weaker affinity for the mobile phase solution. The separation of molecules in the sample results in distinct columns of molecules. The molecules can then be identified with a detector.

One method of detection is mass spectrometry, which utilizes an ion's "mass-to-charge ratio" to provide quantitative information about the compound of interest. First, the researcher will place a sample into a mass spectrometer. The mass spectrometer then converts the molecules into ions. Then, the mass spectrometer measures each ion's mass-to-charge ratio. After each ion has been measured, each ion of a specific mass-to-charge ratio is quantified. The amount of each mass-to-charge ratio is compared to standardized results for the molecules of interest. In addition to the mass-to-charge ratios, the mass spectrometer ascertains the molecular weights of the ions. Information on the molecular weights increases the specificity of the analysis, which is a major advantage of mass spectrometry.

Measurement of biochemical compounds using urine, blood, saliva, or CSF fluid is used to assess their relationship with personality via correlational methods. Commonly, neurotransmitters or hormones are measured and correlated with participants' scores on a measure

of personality such as the Revised NEO Personality Inventory. A quintessential example of this correlational research strategy is the immunoassay of salivary samples to test the role of testosterone in dominant personality traits (Sellers, Mehl, & Josephs, 2007). Sellers and her colleagues found that the amount of testosterone recovered in the immunoassay correlated with the participants' scores on self-report measures of dominance and was unrelated to agreeableness.

As technology has progressed, researchers have developed methods for non-invasive, in vivo assessment of neurotransmitters and hormones active in the CNS. These advances include magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), magnetic resonance spectroscopy (MRS), and positron emission tomography (PET) scans.

Magnetic resonance imaging provides information on the activity of different brain structures by detecting differences in the alignment of nuclei in the scan. Distinct nuclei are identified by detecting the differences in their alignment. These differences are based on nuclear magnetic resonance. All nuclei spin about an axis. The axis of nuclei aligns itself according to its magnetic and chemical environment. In an MRI, the alignment of the nuclei is used to construct the image.

In an MRI, a uniform magnetic field is induced. Nuclei align themselves relative to the magnetic field. Following this, a second magnetic field is induced. The electromagnetic energy of the second field is absorbed by a nucleus, changing its magnetic resonant frequency, the frequency of spin induced by an outside magnetic field. The second magnetic field is repeatedly introduced and removed. Nuclei move between their alignment when the second field is present and when it is absent. Movement between the two alignments is detected by the MRI machine. The differences in the degree of movement are used to construct the image of the brain.

The brain is composed of a variety of structures such as white matter, gray matter, nerve bundles, and CSF. These structures have different molecular compositions which result in different magnetic resonant frequencies. The image produced represents structures with different resonant frequencies with distinct colors. For example, in images produced by an MRI, the CSF will be dark while nerve connections will be white. Modifications of MRI methodology like functional magnetic resonance imaging (fMRI) and magnetic resonance spectroscopy are used for the assessment of the brain's chemical activity.

An fMRI shows differing amounts of blood oxygenation which indicate contrasting levels of activity in separate areas of the brain. Areas with higher levels of blood oxygenation are more active than areas with lower levels. Researchers have used this technique to establish relationships between specific structures in the brain and personality dimensions; these relationships are established by performing an fMRI while a participant engages in a task designed to elicit examples of a participant's personality. For example, in a study designed to discover the brain structures contributing to differences in Big Five personality dimensions in various emotional conditions, participants listened to a piece of music meant to elicit a particular emotion while undergoing an fMRI (Koelsch, Skouras, & Jentschke, 2013). The results of the task and the fMRI are then correlated to determine which brain structures underlie the response given. Further research has revealed that specific brain structures are activated, modulated, or inhibited by specific neurotransmitter or hormonal systems. A classic example of a brain structure being predominantly innervated by a specific neurotransmitter

or hormonal system is the striatal and ventral prefrontal areas. Dopamine is heavily involved in the activity of the striatal and ventral prefrontal areas. Measuring activity in these areas indirectly assesses the activity of biochemicals as they relate to personality.

Magnetic resonance spectroscopy adds to the information obtained with an MRI by providing details about the specific compounds present in the brain. The specific compounds are analyzed by coupling MRI technology with magnetic spectroscopy. Magnetic spectroscopy minimizes the number of signals analyzed by suppressing the signals from nuclei in fat, water, and other extraneous compounds. The remaining signals are quantified, producing information on the concentration of the molecules present. A notable limitation of MRS is that it is unable to quantify dopamine, serotonin, and acetylcholine.

Positron emission tomography is an imaging technique that utilizes radioactive ligands, radioactive molecules that bind to a receptor, to measure concentrations of endogenous neurotransmitters. Researchers using a PET scan to assess neurotransmitter concentration will administer a radioactive ligand that binds to receptors of the neurotransmitter of interest. Compared to the endogenous neurotransmitter, the radioactive ligand must have a lower affinity for the receptor. Because the radioactive ligand has a lower affinity for the receptor, the endogenous neurotransmitter will dislocate the ligand from the receptor. When researchers know the number of receptors in a specific area of the brain, they measure the concentrations of the unbound radioactive ligand. Measuring unbound concentrations of the radioactive ligand provides an indirect measurement of the bound neurotransmitter.

Currently biochemical assessment of personality has a limited role in applied areas such as psychotherapy or counseling. As these methods are refined, and as new methods are developed, we may begin to elaborate on our current understanding of the biochemical basis of personality. A more developed psychobiological understanding of personality can inform pharmacological treatment used in conjunction with psychotherapy. Additionally, refining the methods for assessing neurotransmitters and hormones related to personality expression will have added benefits for research. If we can reliably and accurately assess biological markers for dimensions of personality, we will no longer have to rely on self-report measures, which are complicated by validity issues.

Human Genome Project and Personality

Chelsey Bull and Femina P. Varghese

University of Central Arkansas

The National Human Genome Research Institute (2015a) describes the Human Genome Project as a collaborative international research program created by the National Institutes of Health, Department of Energy, and institutions of higher learning, including those in the private sector, as a way to completely map and understand all of the genes throughout the human body. Mickel and Miller (2011) stated the goal of the HGP was to not only map the genes, but to make the findings available for more research so that the biological foundations of human behavior and personality could be understood.

History

The double helix structure known as deoxyribonucleic acid or DNA was first discovered in 1953 by James Watson and Francis Crick. This is the chemical compound that comprises the genetic instructions for constructing and upholding living organisms. In the 1970s, the methods for "sequencing" the chemical letters DNA were developed (NIH National Human Genome Research Institute, 2015b).

According to the National Human Genome Research Institute, the first draft analysis of the human genome was published in February 2001 in the journal *Nature* by the International Human Genome Sequencing Consortium. The findings indicated that contrary to previous estimates of humans having well over 100,000 genes they were likely to have 30,000. The final draft of the Human Genome Project was successfully completed in April 2003.

The Human Genome Project since its initiation supported the further investigations of the implications of their research including the ethical and social implications. The National Genome Project Research Institute gives notice that all research, including the data, is on the internet and thus readily accessible to anyone around the world. Biotechnology has experienced a revolution as a result of the Human Genome Project with the U.S. now a key leader.

Science

According to the Genetics Home Reference (2016), a genome contains all of an organism's genes. It is the complete set of DNA in all living things. Cells are the fundamental units of function that make up every living system. DNA in the human genome is arranged into 23 chromosomes containing genes, which contain instructions on how to create proteins. Proteins are an important class of complex molecules found in all living cells. Organs need protein as they are vital in carrying out most of the work in the human body. These proteins are made up of amino acids and function as antibodies, enzymes, messengers, transportation, and storage throughout the body. Mutated DNA can produce an abnormal protein, disrupting the body's regular processes, and can lead to the production of a disease. DNA sequencing refers to the process of organizing DNA strands. Sequencing allows scientists to find mutations in genes linked to diseases.

With the vast amount of data generated about human DNA from the Human Genome Project, scientists and clinicians are better equipped in understanding the role that genetic factors play in complex diseases and many other health problems. The HGP does not only provide better information for looking at diseases, but it can also aid in further research on the development of personality.

Personality

The DNA in genes also accounts for what is termed "instincts": inborn behavioral patterns in living organisms crucial to survival. *Intro to Psychology* (2016) states the genes of members of the same species are about 99.9% the same, but the strength of different behaviors and characteristics varies within species. Personality is the result of multiple genes in collaboration and environmental factors. Having a specific gene pattern does not necessarily predict a certain trait, as some traits may only occur in particular environments. For example, a person might have genes that are related to diabetes, but if the person is careful about their diet and exercising then they decrease their risk.

Genes provide us with the biological basis of the set of traits that form the character of a person, also known as personality. The Human Genome Project has created a reliable basis from which the biological components of personality can be measured. The Human Genome Project has created opportunities for research on understanding more deeply how we define ourselves and others. Fitzgerald and Issacs' (2002) research using the Human Genome Project has identified multiple genetic mutations that are associated with personality. Some examples of these personality traits are belligerence, charisma, cynicism, obsessive compulsive behavior, and gullibility.

In 1997, Dean Hamer noted that personality and behavior, ranging from extraversion to alcohol use, have a significant relationship to genes. Preliminary investigations have linked gene Xq28 to color blindness and self-sufficiency. There is also an association between novelty seeking and the gene D4DR. There is also enough variation in serotonin transporter genes to affect a person's level of neuroticism. This serotonin transporter also has associations with alcoholism, depression, and suicidal behavior.

While some traits have been connected to genetic variants, a lot of these variants have astonishingly small individual and cumulative effects, making it extremely difficult to assess early heritability (Maher, 2008). Genome studies are investigating cases in which the heritability is little understood to shed light on personality traits that are heritable versus those that are not (Maher, 2008). The *Canadian Journal of Psychiatry* states that as technology for looking at the human genome steadily becomes more available, it is crucial that obscure personality phenotypes become more clearly defined. Twin research has provided evidence that genetic factors are involved in personality. Through the use of genetic studies researchers can measure more effectively personality phenotypes that correspond with genetic categories.

Behavioral Studies

In order to decide if traits are biological or genetically related, scientists conduct studies of family and non-family members, including twins, adoptees, and siblings. *Is Personality More Nature or More Nurture?* (2016) proposes that essentially, a particular trait is investigated – genetic link is likely if it is most associated with family versus non-family including environments that are shared and not shared. Adoptive studies are particularly helpful, especially in comparing twins raised by the same parents and those not raised together – how similar are they to each other, their parents, and their adoptive parents? These combined data shed light on personality and its relationship to genes. The Human Genome Project was key in initiating the study of personality using molecular genetics.

Developments from HGP

According to the National Institutes of Health, the Human Genome Project can be credited for helping find 1,800 genes related to diseases. It has made the discovery of such genes a much shorter project, whereas in the past it took years to discover such genes. The Human Genome Project is responsible for current tests that allow individuals to assess their genetic risks for various conditions. It also led to the 2005 development of a map or catalog of common variations in the human genome, the "HapMap." The Human Genome Project has also greatly influenced the field of pharmacogenomics. This is an important field that can be potentially life-saving as it investigates how genes influence a person's responses to drugs. The Human Genome Project can even be credited with cost-savings in genome sequencing, along with these discoveries. In addition to creating a drastic decline in the time it takes to recognize genetic patterns and mutations, the Human Genome Project also led to a dramatic decrease in the cost of sequencing whole exomes and genomes.

Future Implications

While the Human Genome Project has led to many important genetic discoveries such as genetic mutations that led to devastating diseases and personality traits that are genetically based, there is still much more research to be done on the human genome in order to determine

more complex diseases and personality traits. The Human Genome Project sparked an interest across the world in scientists to work toward better understanding the entire human genome. One such example reported by the National Institutes of Health is the development of the "Cancer Genome Atlas," a project to map the genetic abnormalities in the major cancers. NIH's Ethical, Legal, and Social Implications Program will be needed even more in the future to develop a model for further research efforts that deal with ethical issues in a positive manner. The ethical and societal implications will be increasingly relevant when connections between genes and non-medical issues including personality and ability are found. Thus, the implications for ethical and social behavior will increasingly become important as we move forward and discover the power of genes.

Model Fitting

Heike Maas

Saarland University, Germany

Studying individual differences in psychological variables, like personality, intelligence, mental health, etc., usually ends up in the description of means, variances and standard deviances or covariances between variables. However, although the description of individual differences or covariances between variables is important, these kinds of analyses reveal nothing about the etiology of individual differences and the etiology of a relationship between variables.

A model stating how genetic and environmental effects contribute to the observed variance in a measured variable makes it possible to estimate the influence of the separate variance components. Model building describes the translation of theoretical ideas into a mathematical form. As such, a model may help to develop appropriate study designs to generate the data which is necessary to test some or all predicated relations.

Model fitting means the statistical process of comparing the theoretical predictions with the actual observations in a given population (Neale & Maes, 2004). If the model fails, the theory or at least part of the theory should be revised. If the model fits, it does not mean that the model is "right" in a general sense, but in that case, the model could be used in further analyses which might broaden the scope of the model.

A model is often depicted as a path diagram, which visualizes linear models for the relationship between variables in a diagrammatic form, e.g. a genetic model, a factor model, or a regression model. Based on such a path diagram, expectations for the variances and covariances of variables in terms of parameters of the proposed model can be easily derived. Furthermore, a path diagram can be easily translated into matrix formulas which are used by the standard programs for behavioral genetic model fitting, like OpenMx.

Conventions of Path Analysis

In a path model, observed variables are denoted by squares or rectangles while circles or ellipses denote latent (unmeasured) variables. Single-headed arrows or paths (->) represent hypothetical causal relationships. Thereby it is hypothesized that the variable at the

tail has a direct causal influence on the variable at the head. Double-headed arrows (<->) represent covariances between two variables and may be used to represent the variance of a variable.

Independent, *predictor*, or *exogenous* variables are those variables that do not receive causal input from another variable in the diagram, while those variables that do receive causal input from another variable are referred to as *dependent* or *endogenous* variables.

Path Tracing

The covariance of any two variables in the model is the sum of all legitimate chains connecting the variables. The numerical value of a chain is the product of all traced path coefficients in it. There are three important rules in path tracing (Wright, 1934) which should be followed.

1) Trace backward then forward or simply forward from one variable to another. Include double-headed arrows from the independent variables to itself. These variances will be 1 for latent variables.
2) Loops are not allowed, i.e. it is not allowed to trace twice through the same variable.
3) There is a maximum of one curved arrow per path. The double-headed arrow from the independent variable to itself is included, unless the chain includes another double-headed arrow (e.g. a covariance path).

The expected variance of a variable (the covariance of the variable with itself) is calculated as the sum of all paths from the variable to itself, following the path tracing rules.

The Classical Twin Model (ACE model)

The variance of a phenotype might be deconstructed into contributions of:

a) Additive genetic effects of alleles at multiple loci (*A*)
b) Genetic dominance effects at multiple loci (*D*)
c) Environmental effects shared by twins or sibling pairs raised in the same family (*C*)
d) Environmental effects that make family members differ from each other (*E*).

The observed phenotype, *P*, will be a linear function of the underlying additive genetic deviations (*A*), dominance genetic deviations (*D*), shared environmental deviations (*D*), and specific environmental deviations (*E*) (Neale & Maes, in preparation).

If only one wave of measurement is used and there are not several variables indexing the studied phenotype, residual effects (like measurement error) will form part of the specific environmental variance component.

As mentioned above, with model fitting in behavior genetics it is possible to disentangle the various factors causing individual differences. The number of effects which can be estimated simultaneously is limited by the number of distinctive predictive statistics. In the
Figure 1 Path diagram for the classical twin model (*ACE*). Parameters *a*, *c*, and *e* are the same across twins and across groups.

classical twin model the available information allows one to estimate at the most three model parameters since there are three distinctive predictive statistics: variance MZ (*VarMZ*), variance DZ (*VarDZ*), and the total variance (*VarP*). Thus, on the basis of twin data it is not possible to estimate genetic dominance effects and shared environmental effects at the same time. An ACDE model would be underidentified and on the basis of reared-together twin data, *C* and *D* would be confounded. As such, it is only possible to estimate genetic effects (additive genetic effects), a^2, genetic dominance effects or shared environmental effects, d^2 or c^2, and specific environmental effects, e^2, at the same time. The twin similarity correlations indicate which of the two components, *A* or *D*, is more likely to fit the data. If the DZ correlation is less than half of the MZ correlation, an *ADE* model might fit the data better. An example for a path diagram fitting the components *A*, *C*, and *E* is shown in Figure 1. The rectangles in Figure 1 represent the actual scores (e.g. sum scores from a self-report inventory for a variable of interest like Extraversion) for each member of a twin pair. The circles represent genetic and environmental factors that might influence the variability of the measured variables: additive genetic effects (*A*), shared environmental effects (*C*), and specific environmental effects (*E*). The straight one-headed paths from the circles to the rectangles represent the hypothetical influences of *A*, *C*, and *E* on the observed variable. These paths are labeled *a*, *c*, and *e*, and the corresponding values are used to compute the heritability estimates and the influences of the shared and specific environment, a^2, c^2, and e^2.

The double-headed curved arrows represent the hypothesized relationship between the latent variables. These values differ for MZ and DZ twins. For MZ twins the curved arrow between the additive genetic effects for each twin would be set at *1.0* because they share 100% of their genetic material (the same would be true for the genetic dominance effects). Because DZ twins share on the average 50% of their genes, the curved arrow between the

Variance of Twin 1 and Twin 2 (for MZ and DZ pairs)

$$a*1*a = a^2+$$
$$c*1*c = c^2+$$
$$e*1*e = e^2$$

Total variance $= a^2 + c^2 + e^2$

Covariance Twin 1 and Twin 2: MZ pairs

$$a*1*a = a^2+$$
$$c*1*c = c^2$$

Total covariance $= a^2 + c^2$

Covariance Twin 1 and Twin 2: DZ pairs

$$a*0.5*a = 0.5a^2+$$
$$c*1*c = c^2$$

Total covariance $= 0.5a^2 + c^2$

Predicted Variance-Covariance Matrix

Cov MZ

	TW1	TW2
TW1	$a^2+c^2+e^2$	a^2+c^2
TW2	a^2+c^2	$a^2+c^2+e^2$

Cov DZ

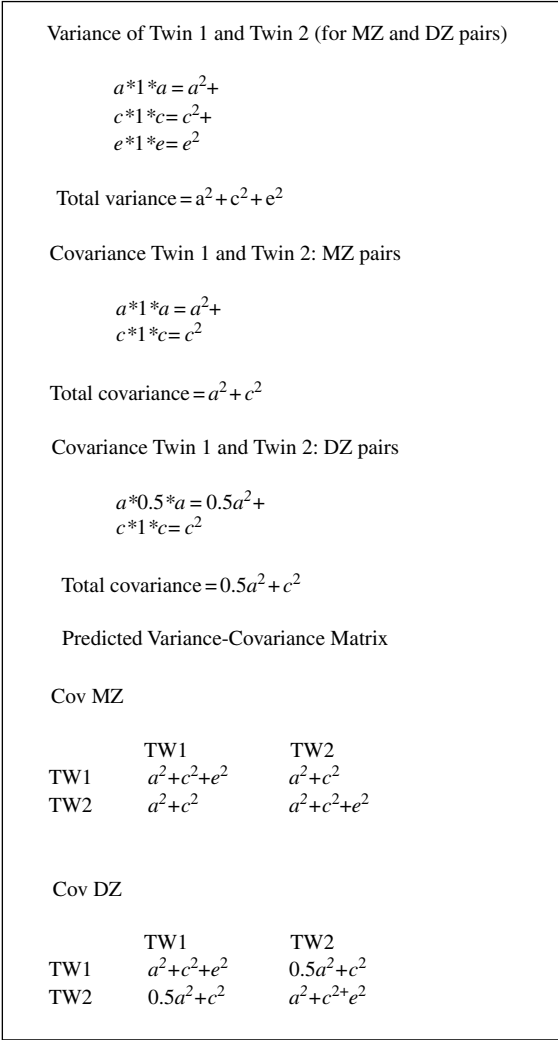
	TW1	TW2
TW1	$a^2+c^2+e^2$	$0.5a^2+c^2$
TW2	$0.5a^2+c^2$	$a^2+c^{2+}e^2$


Figure 2 Calculation of variances and covariances for Twin 1 and Twin 2 for MZ and DZ pairs and illustration or predicted variance-covariance matrices for MZ and DZ twins.

additive genetic effects is set to *0.5*. The similarity for genetic dominance effects is *.25* for DZ twins, as such, this path would be set to *0.25*. The path between the shared environmental effects is set at *1.0* for MZ and DZ twins because in a reared-together twin design, both members of a pair grow up in the same home. There is no path between the sources for specific environmental effects (*E*), because – by definition – these effects are unique for each person (MZ and DZ twins).

In model fitting of twin data, it is furthermore assumed that the values for *a*, *c*, *d*, and *e* are the same for Twin 1 and Twin 2, and that the estimates of *a*, *c*, *d*, and *e* for MZ twins also apply for DZ twins. As such these paths are set equal for Twin 1 and Twin 2 and across zygosity.

How Are Models Fit?

The next question that arises is how the observed twin data fits into such a model. The process of model fitting begins by entering some starting values for a, c or d, and e. We find adequate starting values by estimating heritability and shared and specific environmental effects on the basis of twin similarity correlations. In an iterative process, the computer tests several values of a, c or d, and e. The paths with these values are traced through all of the parts of the model to reproduce the observed MZ and DZ correlations as well as possible. If the model-based correlations come as close to the observed correlations as possible, the iterative process stops and the model is said to fit the data satisfactorily (Jang, 2005). The values for a, c or d, and e that were used to produce the model-based correlations are deployed to compute the influence of genetic, shared and specific environmental effects on individual differences in the observed variable (a^2, c^2 or d^2, and e^2).

The statistical program further determines the degree of correspondence between model-based estimates and observed estimates by "taking the difference between the model-based and actual correlations and weighting it by the sample size of MZ and DZ twin pairs" (Jang, 2005, p. 29). The resulting statistic follows a chi-square distribution, thus chi-square tables can be used to test if the model statistically differs from reality. It should be kept in mind that the goal of model fitting is non-significance. There should be no significant difference between the data the model reproduced and the actual data. If the correspondence between model-based estimates and observed statistics is less than acceptable, the model must be modified and the process starts again. The model may be altered by eliminating hypothesized relationships between variables. For example, if there is no significant effect of shared environmental influences, the fit of the model might be improved if the shared environmental path (c) is deleted. A model can be altered in this way until a satisfactory fit is obtained. The possibility to delete or add paths to a model permits the test of several representations of reality. Of course, the resulting model should still theoretically make sense.

The resulting changes in χ^2 provide a statistical means to evaluate the change. This is the actual basis for model fitting and enables tests of significance of genetic, shared, and specific environmental effects.

In the classical *ACE* model, model fitting begins with the full model. Then the shared environmental effects are deleted from the model to evaluate the resulting *AE*. If this model fits the data as well as the full model, shared environmental effects are not significant and could be left out of the model. Usually, a *CE* model and an *E* model are tested as well to determine which model represents the observed data best.

The *ACE* model can be modified in various ways. For example, if it is assumed that heritability varies by gender, a model could be tested which is usually referred to as *sex-limitation model*. Additionally, it is not only possible to test *univariate* models but also *bivariate* or *multivariate* behavior genetic models. With models like *Cholesky decomposition* the etiology of the relation between two or more observed variables could be estimated.

Because a single heritability statistic might not be adequate to describe the individual differences in the whole population, gene–environment interactions (GxE) should be studied. As described by Purcell (2002), a heritability of 50% could mean that (1) for all individuals, differences in the trait are equally due to genetic and environmental effects, or (2) that for half the population the trait is completely genetically determined while for the

other half individual differences are fully explained by environmental influences. The consideration of GxE helps to distinguish between the two mentioned possibilities. To test a GxE model, the *E* component of the GxE must be a measured variable (Purcell, 2002).

Twin Studies in Personality Research

Laura B. Koenig

Winona State University

Twin studies are used in the field of behavioral genetics (see Behavioral Genetics, General Features and Methodological Issues) in order to estimate the strength of genetic and environmental effects on differences in behavior. Twins are one of "nature's experiments" that can allow researchers to separate the influences of genetic and environmental effects (Plomin, DeFries, McClearn, & McGuffin, 2008).

Methodology

Twins Reared Together

The logic of twin study designs stems from the comparison of two different types of twins. Identical twins, or monozygotic (MZ) twins, share all of their genes because they occur when a single fertilized zygote splits into two. Fraternal twins, or dizygotic (DZ) twins, share only half of their segregating genes (the genes that differ across individuals), and occur when two separate eggs are ovulated and fertilized at the same time. Thus, DZ twins are no more genetically alike than any pair of siblings, although they share a uterus and are of the same age. Comparing the similarity in the two types of twins, therefore, allows for control over age and environmental effects (including prenatal environments) so that differences based on genes can be estimated. Since both twins in each pair are being raised in the same environments, if MZ pairs are more similar than DZ pairs, the conclusion is that there must be genetic effects present that create similarities (and differences) in the trait.

As part of this methodology, researchers can estimate a trait's heritability (see Biological Perspectives), defined as the proportion of differences in behavior that is due to differences in genes. One simple way to do this involves subtracting the DZ twin correlation from the MZ twin correlation and multiplying the result by two. The logic of this calculation is based in algebra which essentially works because MZ twins shared twice as many genes as DZ twins and environments are being controlled, so the difference in the correlations

would be half of the genetic effect and doubling that difference would give the full genetic effect. Twin studies also estimate both shared and non-shared environmental effects. Shared environments make children in the same family similar to one another and non-shared environments make children in the same family different (non-shared environment also includes any measurement error in the trait). Shared environment can be estimated by subtracting the heritability estimate from the MZ twin correlation, since any similarity in MZ twins not due to genetic effects would be due to shared environmental effects (alternatively, shared environmental effects can be found by taking twice the DZ correlation and subtracting the MZ correlation). Any variance left over after accounting for heritability and shared environment would be non-shared environment, such that the three effects would add to 1.0 (or 100%). The heritability estimate calculated this way is a narrow sense heritability, as the calculations assume that all genetic variance is additive (i.e. genes are independently contributing to the trait) as opposed to dominant or epistatic (interactive) effects. Another assumption being made in order for these equations to work is the Equal Environments Assumptions, discussed further below. Another important point is that heritability estimates do not apply to individuals, but to populations. That is, the heritability is accounting for why people are different from one another, not why a particular individual shows a certain pattern of behavior.

More complicated biometric modeling can also be used to calculate heritability and environmental influences, which, instead of using simple algebra, uses the variance-covariance matrices for different types of twins or family relationships and finds the estimates that fit the data best. The model fitting techniques take sample size into account, can examine gender effects, can estimate dominant genetic effects separately from additive effects, and can provide significance and confidence intervals for the estimates.

Twins Reared Apart

A second kind of twin study used in behavioral genetics separates the effect of genes and environments more cleanly: twins reared apart (TRA). These studies involve MZ twins who are adopted at birth and raised in separate homes. Examining how similar these twins are for a trait can help us understand if genes are important in influencing behavior because any similarity seen in the twins must be due to their shared genes. They have not been raised together, so a shared family environment cannot be the cause of their similarity. In this way, TRA provide a direct estimate of heritability. While these twins provide interesting data and are very helpful in understanding genetic effects, the number of such studies, and their sample sizes, are understandably small given the rarity of these twin pairs.

Twin Studies on Personality

Although twin studies of the personality traits of Extraversion and Neuroticism have been most frequent, studies have examined traits from many different inventories, including all Five Factor Model traits (Extraversion, Neuroticism, Openness, Conscientiousness, and Agreeableness; see Big Five), the Eysenck Personality Inventory, the Multidimensional Personality Questionnaire, the California Psychological Inventory, and the Zuckerman

Sensation Seeking Scale, using samples of twins across multiple countries. For various personality traits in various samples, the correlation between pairs of MZ twins is consistently around .40–.50, while the correlation for DZ twin pairs is typically around .20, thus showing genetic effects for personality traits. MZ twins correlate about .40–.50 for personality traits, also supporting a conclusion of genetic influences. Model fitting analyses with twin correlation data lead to the conclusion that around 50% of the differences in personality traits can be accounted for by differences in genes (i.e. a heritability around 50%). This general estimate does not seem to be influenced by the model of personality used, nor does it vary consistently by gender or country of study. The 50% estimate does shift down somewhat, however, when using non-twin methods to estimate heritability (notably family and adoption studies).

Personality in children with traits such as inhibition, shyness, and activity level has also been examined, with findings suggesting that differences in personality at young ages are also partly genetically influenced. A few studies of very young infants, however, have found few genetic effects on personality-related traits, although infant personality is quite different than what is typically measured as personality in adults. In studying the genetic and environmental effects on personality development over time, researchers have concluded that although personality can change across one's life, the stability of personality over time is influenced by genetic effects.

In behavior genetic methodology, a heritability of 50% still leaves 50% of the variance to be explained by environmental effects. A surprising finding in twin studies has revealed that the environment that has the largest effect on personality traits is the non-shared environment, not the shared environment. That is, growing up together does not make siblings similar to one another in personality in adulthood. Researchers have disagreed on what this finding might mean. One interpretation is that environments outside the family home, including peers, are more important in influencing personality and behavior. Another possible interpretation is that siblings in the same home experience contrast and competition effects that make them different from one another instead of similar, and thus, the family matters but not in the way we assume it does. As a related issue, twin studies using parental reports of personality often show much higher heritability estimates that are likely due to contrast effects, where within a family a parent rates MZ twins as being very similar but DZ twins as being more different (where, for example, one twin is thought of as the "outgoing twin" while the other is "quieter," even though the twins' behavior is largely the same). When using behavioral observations, the data collected are less influenced by contrast effects. Thus, some twin studies that have used behavioral reports of personality have found slightly smaller heritability and slightly larger shared environmental effects.

Twin study research on other individual difference personality variables has also been completed, finding genetic effects on differences in relationship quality (e.g. warmth, control, empathy), sexual orientation, self-esteem, attitudes (e.g. traditionalism, political orientation), vocational interests, and happiness and well-being. However, some other variables have shown lower heritability and larger shared environmental influences, including attachment, romantic relationship quality, and religiousness in childhood.

Estimates of heritability found for individual difference traits do not tell us what genes are important in influencing behavior. Twin studies instead provide estimates of an overall genetic effect and whether genes (and environments) are important as an explanation of

why people show different characteristics. Many behavior geneticists are completing molecular genetic studies (see Genetic Bases of Personality) in order to examine what genes on what chromosomes are playing a role for different traits. These studies require sequencing genetic codes not just examining behavioral similarity between relatives of different genetic relatedness. The same is true of the estimates of environmental effects in twin studies – the data tell us only that environments seem to make siblings different, but which environments matter most is not identified. Twin studies also do not tell us the extent to which genes and environments work together to create behavior. Researchers have been designing studies to examine gene-environment interactions (see Gene-environment Interaction) and gene-environment correlations that can help to explain gene-environment interplay. For example, gene-environment correlations reveal that genetic effects are reinforced by environments because people choose and modify their environments in ways that are consistent with their genetic predispositions. Thus, influences that are thought of as genetic might also be environmental. It is certainly true that people with a particular personality choose to be in particular kinds of environments (like someone high on extraversion choosing to go to a noisy party and someone low on extraversion choosing to stay home with a few close friends), and that genes and environments are always simultaneously influencing behavior.

Limitations

Twin studies, like any study, do have limitations. One concern in the twin methodology is the Equal Environments Assumption (EEA). In order for the twin study logic to work, we assume that the environments that MZ twins experience is of equal similarity as the environments that DZ twins experience, such that the only difference between MZ and DZ twin pairs is their genetic similarity. If MZ twins are treated more similarly or have more similar environments, then their excess behavioral similarity might be due to this environment as opposed to their genes. However, tests of the EEA using several different methodologies (e.g. studying similarity in pairs whose zygosity was mis-identified, examining similarity in twins who share more or less measurably similar environments) have generally supported the conclusion that the assumption is an appropriate one to make about twin studies.

Another concern is the prenatal environment that MZ and DZ twins experience and whether both twins in both types of pairs experience similar environments in the womb (as with the EEA). However, research shows that MZ twins are actually more likely than DZ twins to be of different weight at birth. This happens when MZ twins share a chorion (amniotic sac) and/or placenta and have to compete for resources more than DZ twins, who always have different placentas. Thus, this would make some MZ twins less similar with regard to their prenatal development and could not account for why MZ twins are more similar than DZ twins in behavior in childhood and adulthood.

A third concern is whether twins are generally representative of the population at large. If they are not, then the findings of studies using twins might not apply to other non-twin individuals. Twins are more likely to be born prematurely and thus show slower development through infancy, but they catch up quickly. Research has also shown that twins seem to be representative of the general population with regard to the variance they exhibit on most behavioral characteristics, like personality traits.

Behavioral Assessment Techniques, General Features and Methodological Issues

José Santacreu, José M. Hernández, and Víctor Rubio

Universidad Autónoma de Madrid, Spain

The assessment of personality traditionally focuses on measuring traits and dispositions. Such a perspective is aimed at classifying individuals, and an individual's responses are understood to be a reflection of the underlying dimension that is being appraised.

On the contrary, behavioral personality assessment measures the person-situation interaction. Beyond the controversy regarding the consistency of behavior, the main focus of this perspective addresses the interaction as a sample of behavior that an individual might exhibit when faced with a similar situation. Therefore, behavioral personality assessment is aimed at measuring a person's behavior in specific situations.

From a procedural viewpoint, the traditional personality assessment tests use almost exclusively self-reports, while behavioral personality assessment is mainly based on observing and recording the psychological response. Information gathered using personality questionnaires is what the British psychologist R. B. Cattell (1905–1998) called "Q-data."

Conversely, behavioral personality assessment mainly observes and records an individual's behavior in either a natural setting or in a situational lab, in testing and/or in assessment settings. Task-based (i.e. testing settings) performance information is what Cattell termed "T-data." T-data, together with Q- and L-data, which is a person's life record that originates from observations made by others, make up Cattell's three sources of information used to assess dispositional variables.

Behavioral Personality Assessment Techniques

Behavioral approaches have provided an important list of assessment techniques; however, most of them are devoted to assessing the behavior directly involved in the behavioral change according to the main focus of the perspective. Four main types of techniques can be distinguished: self-monitoring techniques, self-report behavioral inventories and

checklists, self-statement inventories, and other forms of assessing thoughts and feelings, and direct observation (Carducci, 2015).

Self-monitoring Techniques

Self-monitoring is the process of observing one's own behavior and producing records of it using self-monitoring cards. Self-monitoring enables a record of occurrence, frequency, intensity and/or duration of a wide range of overt and covert behavior. Self-monitoring techniques facilitate the recording of behavior at the time that it occurs. However, although this is an advantage it is also its major downfall: observing one's own behavior might result in a modification of that behavior.

Self-report Behavioral Inventories and Checklists

Self-report behavioral inventories and checklists typically record the frequency and/or the extent to which individuals are engaged in a series of behaviors in different situations. One very extended example is the Fear Survey Schedule (Wolpe & Lang, 1964) which is aimed at identifying the level of fear a person feels over a range of common situations or stimuli. As standardized procedures, many of them have probed their psychometric properties. Nonetheless, these methods rely on self-reporting by the individual and as such are susceptible to biases.

Self-statement Inventories and Other Forms of Assessing Thoughts and Feelings

When the behavioral approaches started to include cognitive events as antecedents of behavior, many different instruments were designed to assess a person's thoughts and feelings. Some of them are standardized instruments, such as self-statement inventories in which individuals are asked to indicate the extent to which each statement applies to them, e.g. the Automatic Thoughts Questionnaire (Hollon & Kendall, 1980). Others are created ad hoc for thought sampling in specific situations, e.g. What thoughts do you experience when interacting with people of the opposite sex?

Direct Behavioral Observation

Direct behavioral observation consists of a set of procedures in which the subject's target behavior is systematically observed and recorded after developing operational definitions. The methods used for direct behavioral observation range from naturalistic observation in daily life settings, in which observers may or may not be involved, to role playing where the individuals play the role assigned to the assessment purpose, to controlled observation in which structured situations are presented to the person being assessed. The reliability of direct behavioral observation relies on inter-observer agreement whereas its validity relies upon the accuracy of the temporal and situational sampling, as well as the accessibility of the behavior to external observers.

Objective Personality Assessment: A Task-based Assessment

A version of direct observation in a controlled situation specifically designed for the assessment of personality are the so-called Objective Personality Tests, based on the work of Cattell (Cattell and Warburton, 1967). Cattell developed more than 500 objective tests for assessing different personality facets. His aim was to portray personality based on the three sources described above, i.e. "Q-," "L-," and "T-data." However, in spite of his holistic approach to measuring personality and the originality of his tests, there was a lack of correlation between the results from different sources supposedly assessing the same dimension. At about that time, personality psychology was in the middle of the consistency debate originally posed by Mischel (1968). The discrepancy between self-reported data and direct behavioral information led to a bitter controversy about what personality is, and how it can be assessed. This controversy highlighted the lack of a complete and universal model of individual psychological functioning and sent Cattell's attempts to create an objective-behavioral-based personality assessment into oblivion.

Nevertheless, the development of behavioral personality theories going further than the pure analysis of current situations (see Staats, 1996) led to a renewed interest in an objective performance-based personality assessment. This progress was greatly helped by the rise of the interactionist models (Bandura, 1978; Ribes & Sánchez, 1992). These models proposed that behavior is the product of the interaction between an individual with an ontogenetic development, i.e. biological, psychological, and social development, and a specific situation with its specific characteristics. The interaction might produce changes in both the situation and the person. Therefore, changes in behavior are a function of changes in the setting, as the mainstream behavioral outlook has been established, as well as the idiosyncratic characteristics of the person involved.

From this point of view, an individual's personality is shown through consistent and stable behavioral tendencies when facing a specific type of setting. Therefore, assessing personality demands that the measuring procedure does not bias the person's idiosyncratic way of behavior. Otherwise, behavioral tendencies could not be accurately assessed. For example, imagine that we are interested in assessing an individual's tendency to break the rules: Such idiosyncratic behavior could be shown when driving in terms of compliance with traffic lights and signs. However, if a police officer was placed in a visible spot and was watching and giving a ticket to those who broke the law, the lack of transgression is not showing the individual's idiosyncratic behavior, but only the response to the specific characteristics of the setting and the associated contingencies.

Behavioral personality assessment approaches attempt to capture a person's usual way of behaving in order to predict their future behavior when facing an equivalent situation, in which the contingencies do not force only one rewarded response. Consequently, this is a task- or behaviorally-based assessment: the assessment is based on what the person does, instead of what they say they would do.

Designing objective task-based personality assessment tests demands two prerequisites, on the one hand testing the consistency and stability of the behavior related to the dimension under investigation. Therefore, the person should be faced with different settings in order to identify behavioral patterns or tendencies. In other words, if consistent behavior emerged, a direct relationship between the dimension explored, e.g. rule transgression,

risk propensity, impulsivity, thoroughness, etc., and the behavior analyzed can be assumed. On the other hand, choosing a task or a context in which a type of behavior could be expected will be revealed. The specific setting shapes the behavior and consequently, the personality dimensions that could be assessed. This is to say that only those contexts in which individuals have to face alternatives with different probabilities and pay-offs can be useful for assessing risk propensity.

Once the task has been selected, it should enable the person to show different responses all of which would result in the achievement of the goal or reward. For example, if we were assessing risk propensity, the task should allow the individuals to win the same prize irrespective of them opting for a consistent selection of those alternatives with a higher pay-off but a lower probability of occurrence, or for a consistent choice of those alternatives with a lower pay-off but a higher probability.

Because behavioral task-based personality assessment is aimed at assessing an individual's idiosyncratic way of behaving, the recorded response ought not to rely on the person's skillfulness. Otherwise, a different dimension might veil such idiosyncratic tendencies. Similarly, in successive trials, the items or experiments should not foster the individuals' learning in order to avoid test biases.

According to the above, task-based personality assessment tests should join the universal characteristics of ability tests. First, the individuals should be inexperienced in the test situation. In other words, the tasks involved must be novel for the assessees. Second, there should not be any feedback about the person's performance; otherwise, their previous results might affect their subsequent behavior instead of showing the particular individual propensity. Third, the assessment objectives must be veiled. The individuals should not be aware of the number of trials, the results of their performance, or the total length of the test. Regarding the length of the test, Cattell suggested that it should be no longer than five minutes. Finally, the instructions ought to promote the interaction between the individual and the task; therefore they should be clear and accurate. Instructions play an essential motivational role; otherwise, the results would not show the person's idiosyncratic way of behaving but rather a random sample of their behavior, the greater the score range and the larger the inter-individual variability, the better discrimination.

Behavioral Personality Assessment Techniques: Strengths and Limitations

Behavioral approaches center on behavior as the main assessment focus. Contrary to the traditional personality assessment, behavior is not a sign of an intra-psychic characteristic but a sample of the idiosyncratic way an individual behaves. Thus, behavioral assessment emphasizes the systematic observation of behavior.

Behavioral assessment, more focused on behavioral change than on sponsoring a personality theory, has promoted the use of instruments to record the behavior of individuals in a given situation. Therefore, they usually insist on situational characteristics in which the behavior is shown and usually rely on what people do, instead of what people say they usually do. Nonetheless, measurement tool standardization has not been a major concern, coexisting with instruments that psychometrically meet the criteria and some others

created ad hoc. Furthermore, the absence of a generally accepted behavioral personality theory results in a lack of guidelines to indicate which behavior and which contexts should be studied.

However, the recovery of Cattell's objective personality testing tradition has paved the way for the study of personality from a behavioral perspective. First, behaviorally task-based personality assessment should promote new tasks that the individuals are unaware of, and without feedback on their performance in order to prevent any discrepancies in their usual idiosyncratic way of behaving. Second, individuals should be encouraged to cope with the task. Finally, the task must be easy enough to avoid the assessment of ability instead of personality.

Behavioral Assessment Techniques of Personality in Children

Gerin E. Gaskin[1] and Jessica L. Borelli[2]

[1]*Claremont Graduate University*
[2]*University of California, Irvine*

Behavior rating scales and checklists measure the occurrence of behaviors and assess personality and individual differences in youth. Assessment data are used to inform potential intervention strategies and are considered multi-source (i.e. include teacher, parent, and self-report forms) and multidimensional (i.e. assess variety of problems or adjustment issues).

Four sets of behavioral instruments will be discussed in this entry. First, the Achenbach System of Empirically Based Assessment (ASEBA) contains five forms commonly used in child and adolescent assessment. Each rating form contains overlapping groupings or scales across informants (see Table 1). In the parent-report versions of the Child Behavior Checklist (i.e. CBCL/1 ½; CBCL/6–18), parents rate 100 items for children. For older children, parents endorse 113 items and an additional school competence scale. The child's perspective is obtained using the 112-item Youth Self-Report (YSR) scale. For preschool-aged children, teachers or caregivers rate 100 items administered in the Caregiver-Teacher Report Form (C-TRF). Teachers can also endorse 113 items on the Teacher Report Form (TRF) that assess adaptive functioning (i.e. academic performance, working hard, behaving appropriately, learning, and happy), but unfortunately, these data cannot be compared across informants.

The ASEBA scales have advantages and disadvantages as assessment tools. The addition of the Diagnostic and Statistical Manual of Mental Disorders Fifth Edition (DSM-V) scales is beneficial because the scales are based on updated diagnostic criteria. On the other hand, a potential weakness of the instruments is that the normative data is gender-specific. Issues regarding gender norms will be discussed later in this entry. A thorough overview of the normative data, reliabilities, and validities for behavioral scales is included in the "Broad measures of behavioral, social, and emotional functioning and of parenting and family variables" chapter written by Sattler & Hoge (2006) in *Assessment of Children: Behavioral, Social, and Clinical Foundations* (5th ed.).

Table 1 Overlapping Characteristics in the ASEBA Instruments

Measure component	Overlapping characteristics and instruments
Child ages	1 ½–5 (CBCL & C-TRF); 6–18 (CBCL & TRF); 11–18 (YSR)
Scaling	0–2 (*Not true* to *Very true, Often true*)
Total score	Total competence score (CBCL/6–18 & YSR only)
Competence scales	Activities and social (CBCL/6–18 & YSR only)
Syndrome groupings	Externalizing, internalizing, and total problem syndrome (All)
Externalizing scales	Aggressive behaviors (All)
	Attention problems (C-TRF & CBCL/1 ½–5 only)
	Rule breaking behaviors (CBCL/6–18, TRF, YSR only)
Internalizing scales	Somatic problems and anxious/depressed (All)
	Withdrawn/depressed, attention problems, thought problems, and social problems (CBCL/6–18, TRF, YSR only)
	Withdrawn and emotionally reactive (C-TRF & CBCL/1 ½–5 only)
	Sleep problems (CBCL/1 ½–5 only)
DSM-oriented scales	Anxiety problems, attention-deficit/hyperactivity problems, depressive problems, oppositional defiant problems (All)
	Somatic problems, conduct problems (CBCL/6–18, YSR, TRF only)
	Autism spectrum problems (C-TRF & CBCL/1 ½–5 only)

The second group of measures is the Conners 3rd edition (Conners 3). Table 2 illustrates the overlapping characteristics of different versions of the questionnaire by reporter type. The Conners 3 umbrella includes three forms to assess behavior problems with an emphasis on externalizing behaviors. All of the assessments include a full-length and a short version for each rater. Full-length forms are recommended for comprehensive reports and short forms are appropriate when the scale is administered more than once or administration time is limited.

The Conners 3 – Parent (Conners 3–P) short form includes 43 items and the long form has 110 items. Teachers can endorse children on either 39 or 115 items on the Conner's 3 – Teacher (Conners 3–T). The Conners 3 – Self-Report (Conners 3–SR) includes 39 or 99 self-report items and includes a family relations scale. Similar to the ASEBA scales, the scoring for the Conners symptom scales are updated with the DSM-V criteria.

Table 3 displays the third set of assessments. Personality Inventory for Children, 2nd edition (PIC-2) is a questionnaire that assesses behavioral, emotional, cognitive, and interpersonal adjustment for children between the ages of 5–19. Parents rate youth on 275 items that link to nine scales. Each adjustment scale includes two or three subscales and first 96 PIC-2 items can obtain an abbreviated adjustment score for eight of the nine scales.

The Student Behavior Survey (SBS) scales and scoring differ from the scales on the Personality Inventory for Youth (PIY) and the PIC-2 because teachers endorse 102 items to assess children's behavior as well as academic performance and habits. Teachers rank

Table 2 Overlapping Characteristics in Conners 3 Assessments: Full-length (F) and Short (S) Forms

Measure components	Overlapping characteristics and instruments
Child ages	6–18 (Conners 3–P & Conners 3–T); 8–18 (Conners 3–SR)
Scaling	0–3 (*Never, Seldom* to *Very often, Very frequently*)
Scales (S)	Inattention, hyperactivity/impulsivity, learning problems, and aggression (All)
	Executive functioning and peer relation (Conners 3–P & Conners 3–T only)
Indexes	Conners 3 ADHD Index (All, F only)
	Connors 3 Global Index (i.e. total, restless-impulsive, and emotional lability subscales
	Conners 3–P & Conners 3–T, F only)

Table 3 Scales in the Personality Inventory for Children, 2nd ed. (PIC-2), the Student Behavior Survey (SBS), and the Personality Inventory for Youth (PIY)

Measure components	Overlapping characteristics and scale description
Scaling	T/F (PIC-2 & PIY)
PIC-2 & PIY Scales	Cognitive impairment, impulsivity and distractibility, delinquency, family dysfunction, reality distortion, somatic concern, psychological discomfort, social withdrawal, and social skills deficits
SBS Scales	Academic performance, academic habits, social skills, parent participation, health concerns, emotional distress, unusual behavior, social problems, verbal aggression, physical aggression, behavior problems, attention-deficit/hyperactivity, oppositional defiance, and conduct problems
Validity Scales	Inconsistency, dissimulation, and defensiveness (PIC-2 & PIY)

Source: Rowes et al., 2008. Reproduced by permission of John Wiley and Sons Ltd.

academic performance items on a five-point scale (i.e. *deficient, below average, average, above average, superior)*, and endorse other behavioral items using a four-point scale (i.e. *never, seldom, sometimes, usually*). The scoring includes unique scales (i.e. parental participation and support for academics) that support a focus on school context and the teacher's perception of parental involvement. In contrast, because the SBS addresses different factors, comparisons to the PIC-2 and PIY are limited.

Personality Inventory for Youth (PIY) is a self-report inventory consisting of 270 items. Some of the subscales differ from the PIC-2, but overall the assessments are similar and support cross-comparisons. The validity scales in the PIY and PIC-2 help clinicians determine the value of the data. For example, children may display elevated dissimulation suggesting a tendency to "fake bad." Or children may exhibit inconsistency when rating highly correlated items or indicate an inclination of denying common problems (i.e. high scores on defensiveness). Potential limitations of all of the measures are completion time and child fatigue.

The final behavioral instrument, Behavioral Assessment System for Children 2nd edition (BASC-2nd Ed.), is designed to assess personality in youth. The assessments address adaptive and problem behaviors. Overall, the Parent Rating Scale (PRS) and the Teacher Rating Scale (TRS) are considered complementary (see Table 4). Despite the similarities, the PRS has an additional primary scale (i.e. activities of daily living) and the TRS has two additional primary scales (i.e. learning problems and study skills) and an additional composite (i.e. school problems). The SRP differs significantly because the assessment has children rate True/False items in addition to items on a 0–3 scale.

Similar to the PIC-2, strengths of the BASC-2 are the inclusion of a "fake bad" and a Consistency Index. Also, the BASC-2 Response Pattern Index measures the differences of responses in relation to the previous response. A weakness is that clinicians may be unfamiliar with definitions of constructs on the SRP and may require more time to interpret the data.

All of these instruments exhibit measurement strengths and are commonly used to assess youth; however, four general issues exist with behavioral measures. The first issue is referred to as informant discrepancies, or low correlations of responses across informants. More specifically, raters express higher correlated endorsements when they observe a child in similar settings (e.g. teachers and mental health workers) compared with raters who observe children in different settings (e.g. teachers and parents). These discrepancies can be viewed as a source of error (in other words, as a methodological nuisance) or as meaningful information regarding differences in how a child is perceived. Clinicians stress

Table 4 Overlapping Characteristics of the Behavioral Assessment System for Children 2nd Edition Assessments (BASC-2)

Scale components	Overlapping characteristics and instruments
SRP ages	Child (SRP-I) 6–7; (SRP-C) 8–11; Adolescent (SRP-A) 12–21
TRS & PRS ages	Preschool (PRS-P; TRS-P) 2–5; Child (PRS-C; TRS-C) 6–11; Adolescent (PRS-A; TRS-A) 12–21
Scaling	0–3 (*Never* to *Almost always*; All)
Primary scales	Anxiety, attention problems, atypicality, depression, hyperactivity (All).
	Adaptability, aggression, and conduct problems (C & A only), functional communication, leadership (C & A only), social skills, somatization, and withdrawal (TRS & PRS only)
	Attitude to school and attitude to teacher (C & A only), interpersonal relations, locus of control, and relations with peers (SRP only)
Composites	Behavioral symptoms index, externalizing problems, internalizing problems, and adaptive skills (TRS & PRS; C & A only)
	Emotional symptoms index, inattention/hyperactivity, internalizing personal adjustment, and school problems (SRP; C & A only)
Content scales	Anger control (All)
	Bullying, developing social disorders, emotional self-control, executive functioning, negative emotionality, and resiliency (TRS & PRS only)
	Ego strength, mania, and test anxiety (SRP only)
Validity scales	F-index, Consistency Index, and Response Pattern Index (All)

Source: Rowes et al., 2008. Reproduced by permission of John Wiley and Sons Ltd.

the importance of collecting data from multiple sources because the discrepancies represent meaningful differences in the child's interactions with different raters.

Second, disparities in construct definitions across rating scales pose another challenge. Currently, we lack consistent operational definitions that cut across measures; we also lack data showing relationships between construct definitions and critical aspects of child psychopathology (i.e. diagnosis, prognosis, or etiology). For example, externalizing and internalizing symptom groupings are common classes used to understand syndromes in the DSM, rather than the constructs themselves. Moreover, because instruments use different items or subscales across measures, the constructs are incomparable. An awareness of construct differences may benefit clinicians.

Third, the way in which normative data and raw scores are compiled and compared to standardized data is inconsistent across measures. Many tests use separate gender norms, but the BASC-2 provides both combined general norms and separate gender-specific norms. Best norms may depend on the clinical question. Clinicians who are interested in the child's deviance from same age peers may consider using combined gender norms. In contrast, if gender differences are believed to result from a reporting or measurement artifact, then separate norms are a better option.

Fourth, the widespread uses of T scores can create additional challenges. Most report measures communicate results using standardized T scores as scale scores and for comparison purposes. Unfortunately, T scores may be derived in different ways that do not always follow the principles associated with a normal distribution. Moreover, when raw scores are transformed into truncated T scores that include several raw scores, the result is a loss of variability. Thus, researchers should use raw scores for statistical analysis. Finally, best practice should include an awareness of how T scores and standard scores are generated across tests to support accurate interpretations.

Cognitive-Behavioral and Cognitive–Self-Report Assessment Techniques

Leia Friedman and Elizabeth Harwood

Rivier University

Cognitive Behavioral Therapy

Cognitive Behavioral Therapy (CBT) marked a revolution in traditional approaches to clinical psychology. Albert Ellis' Rational Emotive Behavior Therapy (1950s) and Aaron Beck's Cognitive Therapy (1960s) were the first to intentionally recognize the importance of cognition in affecting emotions and behaviors. Both Ellis and Beck examined psychological distress from an empirical lens that was elegant in its simplicity. They hypothesized that irrational thinking (i.e. "I am no good") mediated the relationship between an event (i.e. a relationship break-up) and emotions (i.e. sadness) and behaviors (i.e. isolating, self-harming) related to the event. CBT differed from the complex theoretical models of Psychoanalysis in the early 1900s and the reductionist Behaviorism of the 1940s, and has since been recognized as one of the most empirically supported treatments for depression, anxiety, and a growing number of other psychological disorders.

Assessing Cognition

Cognitive-behavioral assessment studies cognitions, including beliefs and mental images, and behaviors. Beliefs are composed of verbal thoughts (i.e. "they will hear me stutter"). Mental images are sensory representations; imagining that one is stuttering and everyone is laughing (Hales et al., 2015). After identifying cognitions, cognitive-behavioral assessment examines the emotions (i.e. anxiety) and behaviors that follow (i.e. avoiding public speaking) in order to challenge irrational thinking and improve upon behavioral deficits (i.e. avoiding social situations) or decrease behavioral excess (i.e. overeating).

The core concerns of cognitive-behavioral assessment fall into three categories as described by Brown and Clark: internality, accuracy, and accessibility (2015). Internality refers to the abstract, private, and intangible nature of cognition. Although advances in neuroimaging have allowed a closer look inside the brain, and cognitive assessments are

constantly being examined, reworked, and refined, it is unlikely that any measure will ever be able to objectively quantify cognition. Accessibility is the second obstacle: can the client access and identify their cognitions as requested in the assessment? Cognitive assessment tools will not work for all clients or participants, as limitations may exist in the way of language, vocabulary, insight, motivation, etc. Also of concern is accuracy. Individuals may believe they are accurately reporting their experience of the event, but human memory is not infallible and is subject to distortion, especially over time (Loftus & Palmer, 1974). The subjective nature of language and the potential for insincere reporting are also concerning.

Informal Assessment

Informal assessment includes self-monitoring techniques such as filling out thought records or diaries. For example, Albert Ellis created the ABCDEF model in which clients identify and record: (A) the *A*ctivating event, (B) *B*eliefs surrounding the event, (C) emotional and behavioral *C*onsequences of beliefs, (D) *D*ebating the irrational beliefs, (E) the *E*ffect of debating the beliefs, and (F) the new *F*eeling that is created (Ellis & Dryden, 2007). In his book, *Feeling Good: The New Mood Therapy,* Burns (2008) created the triple column technique based on Beck's Cognitive Theory. The client (1) writes down critical thoughts, (2) identifies distortions, and (3) talks back to these distorted thoughts. Other helpful assessment tools include saying thoughts aloud, recording thoughts with "thought listing," "thought sampling," or "event recording," or monitoring thoughts (in vivo self-reports; Cacioppo & Petty, 1981; Davi son, Vogel, & Coffman, 1997).

Formal Assessment

More formal self-report assessment measures exist and some can be syndrome specific. Several established instruments are categorized and briefly described below.

Other Means of Assessment

Cognitive Functional Analysis (Meichenbaum, 2003) examines an individual's internal dialogue, including what occurs before (the antecedent) and after (the consequence) the dialogue. For example, a person may be anxious when they return to their hometown (antecedent), making self-statements such as, "my old classmates will think I'm a failure," and as a result drink excessively (consequences).

Physiological data is also used in cognitive assessment (Berntson & Cacioppo, 2004). Biofeedback can measure the bodily functions of an individual and provide feedback about their physiological state, such as their heart rate, galvanic skin response, blood pressure, etc. A portable biofeedback device which measures heart rate has been an effective complement to CBT for people with anxiety (Reiner, 2008) With increasing technological advances, biofeedback is likely to become more sophisticated and accessible, perhaps improving the reliability and validity of cognitive assessments.

Table 1 Examples of Formal Assessments

Disorder	Inventory	Authors	Description
Depression	Attributional Style Questionnaire	Peterson, Semmel, von Baeyer, Abramson, Metalsky, & Seligman, 1982	Measures attributional style; participants report their reactions to six positive and six negative events
	Automatic Thoughts Questionnaire	Hollon & Kendall, 1980	30 items; measures frequency of maladaptive thoughts
	Beck Depression Inventory-II	Beck, Steer, & Brown, 1996	21 items; measures cognitive, emotional, and physical symptoms of depression
	Dysfunctional Attitudes Scale	Weissman & Beck, 1978	40 items; measures maladaptive beliefs/schemas identified by Beck
	Beck Hopelessness Scale	Beck, 1988; Beck & Steer, 1993	20 items; rates how pessimistic the individual is towards the future; indicates a person's level of depression
Anxiety	Anxious Self-Statements Questionnaire	Kendall & Hollon, 1989	32 items; records content, frequency, and severity of specific anxious thoughts
	Fear Survey Schedule - III	Wolpe & Lang, 1977	Measures level of anxiety/fear of stimuli. Several adaptations exist for use with children, adolescents, adults and those with intellectual disabilities
	Irrational Beliefs Test	Jones, 1968	100 items; measures irrational beliefs
Eating disorders	Eating Attitudes Test - 26	Garner, Olmsted, Bohr & Garfinkel, 1982	26 items; screening instrument for eating disorders; three subscales: "dieting," "bulimia and food preoccupation" and "oral control"
Social skills	School Social Behavior Scale -2 and Home and Community Social Behavior Scales	Merrell, 2008; Merrell & Caldarella, 2008	Both have 65 items that measure a child's social-emotional strengths and risky behaviors at school, home and the community on two major scales: social competence and antisocial behavior
	Wolpe-Lazarus Assertiveness-Scale	Wolpe & Lazarus, 1966	30 items; measures assertiveness
Measures for children	Children's Depression Inventory-2	Kovacs, 2010	28-items; assesses depression in children
	Multi-dimensional Anxiety Scale for Children-2	March, 2012	50-item self and parent forms indicate symptoms related to anxiety disorders for ages 8 to 19 years old

Psychometrics: Issues with Reliability and Validity

Reliability and validity assess the psychometric soundness of an instrument. The reliability of retrospective self-report on one's own cognitions is limited. A person's ability to attend to and observe their thoughts and emotions as well as articulate them may fluctuate based on mood, stress, honesty, introspective ability, and different interpretations of rating scales between test takers. Owing to the difficulty communicating with children about such abstract topics as cognition and emotion, the assessment of psychopathology in children is more focused on overt behavior than internal thoughts.

The strengths of self-report inventories are that they have strong face validity and are easy to administer and to score. Whether or not the measure is actually valid is established through a variety of methods, including statistical analysis and empirical research. Owing to CBT's emphasis on empirical validation, it is not surprising that many of the formal assessments mentioned above have established their psychometric soundness. The Beck Depression Inventory (BDI; Beck, Steer, & Brown 1996) is one of the most empirically studied cognitive assessments of depressive symptomatology. It has strong internal consistency ($\alpha = .92$) and high concurrent validity ratings with other depression instruments such as the Hamilton Depression Scale (Beck et al., 1996).

Cross-Cultural Considerations

Cognitive-behavioral measures have not been sufficiently studied across a broad range of cultures (Bemal & Scharrón-del-Río, 2001). Assessing when a thinking style is "problematic" is difficult due to variance in social norms, language, and cultural values in diverse populations. Helms (1992) has argued that cognitive assessment often defers to an "unacknowledged Eurocentric perspective," and instrument developers should coauthor with other professionals with expertise in multicultural topics rather than sufficing to mention that instruments may not take into account the full spectrum of cultural considerations.

Whether the client belongs to a collectivist or individualist culture can influence the results of a cognitive assessment (Brown & Clark, 2015). For example, people from individualistic nations reportedly draw from their own subjective emotional experiences to understand their cognitions and emotions, whereas individuals from collectivistic countries rely more heavily on cultural values as a basis for such judgments. Assessment in diverse populations can include various types of Cognitive Functional Analysis, such as for depression (Ferster, 1973) or avoidance (Hayes, Wilson, Gifford, Follette, & Strosahl, 1996), the Culturally Informed Functional Assessment (CIFA; Tanaka-Matsumi, Seiden, & Lam, 1996), and the Multicultural Assessment Procedure (MAP).

Current Trends in Cognitive-Behavioral Assessment

Current researchers face the challenge of maintaining the research momentum as advances in cognitive assessment are critical. Connecting cognitive-behavioral assessment with neuroscience (neuroimaging, biofeedback, pharmaceutical interventions, etc.) may be a fruitful area to explore in this endeavor. Additionally, recent research has indicated that mental imagery has a greater impact on both negative and positive emotions than previously

thought (Holmes, Mathews, Dalgleish, & Mackintosh, 2006), which requires further study on how to accurately assess it. Furthermore, greater emphasis on collecting real-time cognitive content in the naturalistic setting is needed (i.e. thought sampling), especially in light of the new opportunities afforded by apps and smartphone technology, such as iCBT, an internet CBT tool developed to modify biases and reduce negative thinking using a simple computer program (Andrews, Cuijpers, Craske, McEvoy, & Titov, 2010).

Self-monitoring Behavioral Assessment Techniques

Amy Hufstedler and Femina P. Varghese

University of Central Arkansas

Conceptualizations

According to prior reports, including one by Jo Webber and colleagues in 1993, self-monitoring techniques involve a client observing and somehow noting their own behaviors, feelings, or thoughts. The information that is monitored could be quantitative or qualitative in nature. As a behavioral method of assessment, self-monitoring has been observed as an effective method that allows for a firsthand assessment of one's internal and external thoughts, feelings, and behaviors. Self-monitoring techniques can provide assessment, change, or maintenance of behavioral patterns. Whether done electronically, on paper, or even by merely acknowledging one's conscious thoughts, self-monitoring can play a role in assessment that retrospective or externally administered methods cannot. It can also play a role in clinical practice and has been used extensively in Cognitive Behavioral Therapy (CBT) interventions (for further elaboration on these see Cohen, Edmunds, Brodman, Benjamin, & Kendall, 2013).

A General Description of Self-monitoring Techniques

Webber and colleagues in 1993 provided a history and description of self-monitoring. Self-monitoring was primarily used for research purposes, allowing participants to self-report data. This assessment method also provided a practical and otherwise unobtainable measurement of the frequency of certain target behaviors. Over time it has additionally been used as a method for actually *changing* behavior (including an instance of changing oral self-care behavior documented by Schwarzer, Antoniuk, & Gholami, 2015). Also, self-monitoring allows for the collection of data involving unseen or abstract behaviors such as thoughts, desires, or ideations. Webber and colleagues (1993) note that self-monitoring assessments can include noting each incident of a behavior or assessing a behavior using an external set of criteria. The act of self-monitoring may be prompted in different ways. Some methods will rely on an external prompt, such as a physical cue (a tone or a visual signal) that signals

to the person that they need to record the target behavior/thought/feeling at that time. Another method is internal, or self-prompted, where the person makes a recording whenever they think about it, as noted by Peterson & Tremblay in 1999, and Webber et al. in 1993. Self-monitoring has been utilized as a behavioral technique to reduce problem behaviors for a variety of issues including diet, smoking, and weight gain in children and adults. Existing theories have attempted to explain the effectiveness of self-monitoring techniques and how they might produce lasting changes in behavior. Three such theories are described in a review by Webber, Scheuermann, McCall, & Coleman in 1993, and are summarized below.

Theories of Self-monitoring and Behavior Change

Several theories have been proposed to explain the effectiveness and processes of self-monitoring; three of the more prominent are described by Webber and colleagues in their 1993 article. One states cognitive self-awareness of behavior is powerful enough to change behavior due to cognitive processes. Another indicates that reactivity, or behavior change, occurs in response to the activating event of self-monitoring, and that consequences are developed internally by the person. The mere monitoring, according to this view, has turned into a means by which one will feel reinforcement or punishment based on internal constructions. Still another assumes that the procedures of self-monitoring cause change because they serve as prompts. Therefore both behavioral and cognitive factors play a role in the efficacy of self-monitoring techniques.

Content of Typical Self-monitoring Assessments

The purpose of self-monitoring is the collection (and potential use) of information, and this information may exist in various forms. Barton and colleagues state in their 1999 report that multiple categories of self-monitoring exist, and that articles using self-monitoring as a data collection method have gathered various types of information from participants. The following section describes some different types of information self-monitoring can provide.

Behaviors

One type of self-monitored information is behavior. Self-monitoring behaviors involves bringing certain behaviors into conscious awareness for a variety of purposes. Some examples of behaviors one might self-monitor include:

- The number of sodas you drink in a particular week
- How many times you shake someone's hand at work
- The number of cigarettes you smoke each day
- How often you shower
- How frequently you say "um" in a conversation

There are many "recordable" behaviors that can be self-monitored. Self-recording the frequency, location, timing, etc. of behaviors could allow an individual to increase awareness

of the behaviors, identify and acknowledge their maladaptive effects, or even change or eliminate them.

Thoughts or Cognitions

Another type of information that can be self-monitored includes cognitive factors such as thoughts and feelings. Cohen and colleagues in 2013 describe the importance of self-monitoring techniques to CBT interventions, which place a heavy emphasis on the role of thoughts in associated feelings and behaviors. An individual might monitor thoughts to bring maladaptive, disruptive, or impractical thoughts into consciousness and allow for acknowledgment that these thoughts are leading them to feel or behave in a certain way. This identifies an advantage of self-monitoring over other forms of monitoring (such as an objective observer or remembering past behavior) because thought monitoring is not something that can be done externally, and thoughts cannot be accurately collected an observer. Rather, this information is self-reported. Some examples of self-monitored thoughts might include the results of asking a participant to record each time they:

- Think about suicide
- Think about their mother
- Think about wanting to smoke a cigarette
- Think about an ex-partner
- Think about eating food

The identification or conscious awareness of thoughts and their frequency could provide insight that leads to increased self-understanding and behavior change, and this information has been of particular interest in CBT interventions, as noted by Cohen and colleagues in 2013.

Feelings and Emotions

An individual's in-the-moment feelings and emotions might also be reported using self-monitoring. Typically, spontaneous self-reported feelings and emotions are collected using established measures designed to assess specific feelings or emotions. One such measure is the State Trait Anxiety Inventory, which assesses in-the-moment anxiety symptoms. Another example of the collection of self-reported emotions is described by Tsanas and colleagues in a 2016 study. The authors introduced a smartphone application called Mood Zoom, which would provide a "real-time" mood report based on time-stamped prompts provided by the application. This allowed the researchers to gather immediate information about the following: anxiety, elation, sadness, irritability, and anger. The collection of feelings and emotions can inform mental health professionals and other clinicians, as well as researchers.

Physiological Recordings

Physiological information is another type of information that can be self-monitored, and is particularly useful for medical purposes (although it has been the focus of many psychological research studies as well). Barton and colleagues (1999) describe the collection and

use of many physiological factors. Some possible examples of the content of physiological self-monitoring include:

- Heart rate, measured by counting one's heartbeats per minute (i.e. someone who wants to maintain a certain heart rate while exercising or someone who suffers from panic disorder who uses their heart rate as a way to assess the onset and termination of a panic attack)
- Blood pressure (i.e. someone with chronic high blood pressure who uses a blood pressure cuff to monitor during the day)
- Sweat (i.e. those who note the presence of sweat to indicate anxiety or stress)
- Temperature (i.e. using a thermometer to track one's temperature during an illness).

The collection of self-monitored physiological information has developed rapidly in complexity and accuracy over time. This is primarily due to the rapid expanse of healthcare technology, and the portable and easily accessible nature of the necessary recording tools. This has various implications for psychological research as well, as many different physiological changes are associated with certain psychological states.

Types of Reports in Self-assessment

Quantitative

Some information gathered using self-assessment is quantitative or numerical. This can include frequencies of thoughts or behaviors, amounts of time, the numerical intensity of a feeling, etc. Advantages of numerical data include the general ease and speed of collection on the part of the individual, and the speed of analysis of numerical data on the part of the researcher or clinician. Numerical information can also be clearly defined for the individual in terms of behavior change interventions (i.e. a therapist setting a goal for an individual to reduce a maladaptive action from a frequency of three times daily to once daily).

Qualitative

In contrast to quantitative or numerical information, qualitative information can be self-monitored and self-reported as well. Examples of qualitative information may include journal entries, in which a person records what they are doing, how they are feeling, etc. at designated intervals over time. It also might involve identifying feelings or thoughts in response to certain events or stimuli. Advantages to qualitative data include the potential for thorough and subjective reports of an individual's experiences.

Advantages and Limitations of Self-monitoring

Advantages

In some situations, self-monitoring is a practical and parsimonious method for either collecting information or producing behavior change. Advantages to this method have been described by Barton and colleagues in 1999, Cohen and Colleagues in 2016, and Peterson

and Tremblay in 1999. One such advantage exists when the desired information cannot be ethically observed or recorded by anyone other than the participant. To elaborate, consider the assessment of a person's late-night eating habits, sexual behaviors, or instances of drinking while alone. In such situations, self-monitoring is instantaneous and around-the-clock, and can therefore serve as a practical observation method in "unobservable" situations. Another advantage of the instantaneousness of self-monitoring is that retrospective reflections or reports are not required; therefore, any errors in remembering can be minimized. An additional benefit is the temporal consistency of self-monitored information, especially with the use of external cues (i.e. the smartphone notification used by Tsanas et al. in 2016). Finally, self-monitoring also limits the effects of the person's reactivity to an observer, therefore minimizing experimenter bias.

Limitations

Alternatively, there are some significant limitations that cause concern when considering self-monitoring as a data collection, assessment, or intervention method. Barton and colleagues in 1999, Peterson and Tremblay in 1999, and Stewart and colleagues in 2000 provide a description of some of these limitations, and describe deficits that might be encountered. When people report their own behavior, with no external observation, there is no complete assurance that the information provided is accurately or honestly reported. For example, if an individual were asked to monitor his or her drinking habits, they could potentially underreport based on shame or fear of judgment. Self-monitoring may therefore produce inaccurate reports, particularly concerning sensitive subject matter. Another limitation is subjectivity of information. If the individual has not been given specific instructions or trained regarding what information to record (and how and when to record it), there could be missing information or skewed data. Also, self-assessment and self-monitoring is a biased report due to the individual's beliefs about themselves, and therefore information might be skewed based on these beliefs. A final potential limitation is internal motivation versus external motivation, and how one might be more effective than the other.

Considerations for Specific Populations

Self-monitoring will have varying levels of consistency and effectiveness depending on the population. Research utilizing self-monitoring methods acknowledges that population differences can affect the integrity of the information gained. For example, those who suffer from antisocial personality disorder might be less motivated to truthfully self-assess than those who do not, so self-monitoring might not be the most effective strategy. Also, as mentioned, when dealing with sensitive information such as drug abuse, criminal behavior, sexual activity, or excessive drinking habits, there is an increased likelihood of falsified or exaggerated reports. This might also affect self-monitoring if the individuals are in denial. Peterson and Tremblay (1999) report that providing inaccurate data can happen with any age group, but children might particularly lack self-awareness of their actions. Further, *any* group which is not adequately motivated might not self-monitor correctly. Burk and

colleagues noted in a 2011 review that men are generally more compliant with self-monitoring than women, so gender differences when self-monitoring should be considered.

Future Considerations

A large influence on the expansion in prevalence and complexity of self-monitoring techniques has been the development of smartphone applications and other electronic personal monitoring tools. A review by Lyons and colleagues in 2014 provides a thorough examination of certain self-monitoring methods using electronic devices. The authors acknowledge that with the ever-increasing number of available smartphone apps, self-monitoring is increasingly easy to do and can require little to no effort. Within seconds, a person can report any sort of information to an application (such as the aforementioned Mood Zoom) in a prepared template that allows them to monitor various aspects of their day. Another popular example of these is fitness monitoring applications such as Fitbit. The user wears a bracelet that synchronizes with an app on their cellphone. At any time, the user can look at their phone and see how many steps they took that day, how many stairs they climbed, their heart rate fluctuations throughout the day, and how many minutes of their day were spent being active, among many other features. Smartphone applications have been developed to assist with everything from breastfeeding ("Baby Nursing") to anxiety ("SAM") to lawn care ("My Lawn"), and everything in between. Empirical research has assessed the effectiveness of many such self-monitoring methods, including a study by Turner-McGrievy and colleagues in 2013 that assessed weight loss applications, a study by Tran and colleagues in 2012 that assessed blood glucose-monitoring applications, and a study by Cohn and colleagues in 2011 that assessed an alcohol use application. This can be advantageous for research as well as for the consumer, as data can be collected reliably and translated easily for study purposes, with a small amount of outside influence or interaction by a researcher or laboratory setting.

Assessment of Intelligence, General Features and Methodological Issues

A. Alexander Beaujean and Nicole Woodhouse

Baylor University

There is perhaps no area in psychology with a longer history, larger corpus of research, and more contention than the assessment of intelligence. Modern intellectual assessment was largely born in the late nineteenth century. Initially, the tests were designed to aid in the teaching of students, and later they were adopted by organizations to aid in personnel selection.

Developers of current intelligence instruments – especially those commercially available for clinical use – often follow best practices in their design. They tend to use large and representative samples, use items that measure their intended constructs well, and produce unbiased scores. Thus, these instruments tend to provide scores that reliably and validly measure the constructs they intend to measure. Nonetheless, there have been some issues that have continually pervaded the assessment of intelligence.

Defining Intelligence

An important aspect in the test development process is being able to define the construct the test intends to measure. However, psychologists have never agreed on a definition of *intelligence* or the components involved in its makeup. This is not for lack of trying, as there have been many books and conferences designed to aid in developing such a definition.

Some have argued that this lack of agreement on a theory and structure of intelligence is the major reason there are so many different intelligence tests. Many current tests are designed to be comprehensive measures that quantify some overlapping components and yield a general factor (*g*; Spearman, 1927) that is somewhat similar across instruments. Other tests are grounded in contradictory perspectives, such as the planning, attention-arousal, simultaneous, and successive (PASS) theory, dynamic assessment, or Triarchic theory.

In 1993, John Carroll published a meta-analysis that examined the relations among multiple measures of different aspects of cognitive ability. In this study, he factor analyzed over 400 datasets and the results led him to develop a three-stratum theory. His theory postulates that intelligence is a multifaceted concept, and that all cognitive tests measure some aspects of intelligence common to other tests. At the first level (Stratum I) are specific abilities (e.g. induction, quantitative reasoning). These abilities are not very abstract and can often be determined by the content of the tests that comprise the factors. At the second level (Stratum II) are factors that are related to a small number of primary or group abilities (e.g. fluid reasoning). At the third level (Stratum III) is a single general factor: *g*.

Carroll's work was monumental on multiple levels, especially for the field of intellectual assessment as it provided an empirical solution for understanding intelligence. His taxonomy provided a common conceptual structure for understanding the construct. Moreover, he provided a nomenclature to describe what the panoply of cognitive tests measure.

Level of Interpretation

Related to the definition issue is the dispute of the level at which intelligence test scores should be interpreted. This debate started in the early twentieth century with those from the "British" tradition arguing that intelligence should be interpreted at the general level, with *g* being the most important aspect. Those from the "American" tradition argued the opposite: interpretation should primarily reside at the specific/group factor level. While the original argument was largely between factor analysts, the issue soon moved into the clinical arena.

The original Binet intelligence tests yielded a single developmental age score for each examinee; thus, there was little debate about what score to interpret. The World War I Army Alpha and Beta tests took a somewhat different approach, as they required examinees to complete multiple homogenous subtests. Nonetheless, interpretation was focused solely on a single score aggregated from the subtests. David Wechsler was strongly influenced by the Army tests, so when he developed the Wechsler–Bellevue Scale, he made the scoring such that both the subtests and the aggregate score were standardized and interpretable, although Wechsler initially only advocated using the global score clinically.

Soon after the Wechsler–Bellevue Scale's publication, some clinicians began arguing for interpreting non-global measures on the test, such as subtest scores and item responses. They believed information from the non-global scores, especially intra-individual comparisons (e.g. differences in item performance and subtest scores), were meaningful to interpret and could enable clinicians to make better diagnostic decisions.

The intra-individual comparisons approach was not universally accepted as Jacob Cohen, among others, argued that most Wechsler subtests did not have enough specificity to warrant their interpretation. Through a series of exploratory factor analyses (e.g. Cohen, 1959), he found that most of the subtests' reliable variances could be explained by *g*, with some group factors explaining most of what was left over. Thus, the amount of reliable variance attributable to what is unique to subtests is too minimal to warrant any clinical use.

The same argument about the level at which to interpret intelligence tests continues today. Some continue to argue that the global scores from intelligence tests are of minor clinical use and should either not be interpreted or should be interpreted in light of any variability in the index or subtests scores. Instead, they argue that it is the pattern of the index scores (or subtests) that allows clinicians to best understand the examinees' cognitive functioning and, subsequently, develop interventions.

In contrast, others argue that factor analysis of modern intelligence tests indicates that the global score should carry the main interpretative weight as it has the most reliable variance. Like Cohen, they contend that the amount of unique variance attributable to index scores or individual subtests is too small to interpret clinically. Moreover, the incremental validity that index or subtest scores add beyond the global score is so minimal that it is not clinically useful.

Clinical Importance

Undoubtedly, intelligence is important to modern life, as it is correlated with a variety of important outcomes and can predict success in many endeavors. Still, the question remains about how clinically important it is to know an individual's intelligence. Specifically, does knowing an individual's intelligence aid in making diagnoses or developing interventions?

Indisputably, measuring intelligence is important when determining if an individual has an intellectual disability or some other cognitive impairment. Its importance in making other diagnoses, however, is typically either irrelevant or questionable.

With interventions, there is evidence that intelligence is important to consider in the overall structure of education. Specifically, individuals with lower levels of *g* require more intensive instruction (e.g. more practice, repetition, examples) than those with higher levels of *g*. Beyond *g* (i.e. Stratum I or II factors), there is much more debate about the clinical usefulness of intelligence. Some argue that it is important to know an individual's profile of scores in order to develop appropriate interventions, while others believe there is little to be gained by developing interventions based on index or subtest scores.

Outside of education, the treatment validity of intelligence is much weaker. Intelligence is related to resilience and long-term effectiveness of psychological interventions. Nonetheless, there appears to be little evidence to support the idea that treatments should differ based on level of intelligence.

Stanford-Binet Intelligence Scale: Fifth Edition

Kristina C. Peterson, Matthew Peterson, and Bernardo J. Carducci

Indiana University Southeast

Overview

The Stanford-Binet Intelligence Scale was created as a modified version of the Binet-Simon Scale of Intelligence (Marom, 2003). The original test was created to evaluate an individual's complex mental abilities (memory, abstraction, judgment, reasoning) in order to assess and diagnose mental retardation. Since the Binet-Simon Scale of Intelligence was published in France translations were later made for use in other countries. However, the English translation proved to be problematic. Lewis M. Termin created the most comparable translation to the original scale, which is still used to this day (Canivez, 2009).

The Stanford-Binet Intelligence Scale – Fifth Edition (SB5) tests the intelligence and/or the cognitive abilities for individuals ranging in age from 2 to 85+ years. There are multiple scores within this intelligence scale, including Full Scale IQ scores, Abbreviated Battery Scores, Verbal IQ Scores, and Nonverbal IQ Scores. Ten subtests are administered during the test, which provides five Factor Index scores that correspond with the five factors examined in this scale. The complete test takes approximately 45 to 75 minutes to administer. However, the Abbreviated Battery takes only 15–20 minutes to administer. The Abbreviated Battery was created to allow for a quick assessment of general intellectual abilities using both non-verbal fluid reasoning and verbal knowledge subtests (Cohen and Swerdlik, 2010).

The SB5 measures five factors of intelligence based on the Cattell-Horn-Carroll (CHC) theory of intellectual abilities. The factors from the SB5 are: Fluid Reasoning (FR), Knowledge (KN), Quantitative Reasoning (QR), Verbal-Spatial Reasoning (VS), and Working Memory (WM). These are measured using varying levels of subtests and tasks. Table 1 provides the description of each factor and the CHC equivalent. This edition of the Stanford-Binet Intelligence Scale has made an effort to eliminate bias by creating subtests that evaluate multiple levels of language ability depending on the amount of vocal direction needed. Some uses of the SB5 include assessment of mental retardation, learning

Table 1   SB5 and CHC Factors

SB5 Factor name	Description	CHC Factor name
Fluid Reasoning (FR)	Novel problem solving; understanding of relationships that are not culturally bound	Fluid Intelligence (Gf)
Knowledge (KN)	Skills and knowledge acquired by formal and informal education	Crystallized Knowledge (Gc)
Quantitative Reasoning (QR)	Knowledge of mathematical thinking including number concepts, estimation, problem solving, and measurement	Quantitative Knowledge (Gq)
Visual-Spatial Reasoning (VS)	Ability to see patterns and relationships and spatial orientation as well as gestalt among diverse visual stimuli	Visual Processing (Gv)
Working Memory (WM)	Cognitive process of temporarily storing and then transforming or sorting information in memory	Short-Term Memory (Gsm)

disabilities, developmental disabilities, and intellectual giftedness. However, in order to diagnose mental retardation the individual needs to also be assessed for serious deficiencies in adaptive behaviors (Cohen and Swerdlik, 2010).

Standardization

The final standardized edition of the SB5 was established after five years of development and analysis to address possible biases, such as racial/ethnic, gender, cultural, and religious discriminations. Roughly 500 examiners from all 50 states were trained in administering this test. There were 4,800 subjects in the average sampling group that ranged from 2 to 85+ years of age. Based on the year 2000 U.S. Census data, the sample was nationally representative of all demographic factors, including age, geographic region, race/ethnicity, and socio-economic level. The original study did not make accommodations for individuals with special needs; however, they were accounted for in further studies. Some individuals were excluded from the original standardized sample if they had severe sensory or communication deficits, limited English proficiency, severe emotional/behaviors disturbances, and/or severe medical conditions (Cohen and Swerdlik, 2010).

Reliability and Validity

An interval consistency reliability formula was used to assess the reliability of the SB5 Full Scale IQ. The results showed that the coefficients for the Full Scale IQ were consistently high (.97 to .98) across all age groups. The Abbreviated Battery IQ scale was also tested and results showed that it was also consistently high (average of .91). Researchers also examined the test-retest reliability of the SB5 and found high reliability. However, the interval was

only 5 to 6 days, whereas other comparable tests were done with a 20–25-day interval. Inter-scorer reliability was also investigated and the results ranged from .74 to .97 with a median of .90. The questions that showed particularly low inter-scorer reliability were removed from the edition of the test (Cohen and Swerdlik, 2010).

The content-related validity for the items in the SB5 was examined in multiple ways, including expert opinion and empirical analysis. The criterion-related validity was tested and evidence was revealed in both predictive and concurrent forms of data. Concurrent studies were compared between the SB5 and Stanford-Binet: Fourth Edition (SB:FE), as well as with all three Wechsler batteries. The correlations between the SB5 and SB:FE were high but, unsurprisingly the correlations with the Wechsler tests were not as high (Cohen and Swerdlik, 2010).

Test Administration

In order for intelligence tests to be sensitive to all individuals, especially children, developers of these tests have tailored them to the test takers. This type of testing is known as adaptive testing. Other names for adaptive testing include response-contingent testing, branched testing, sequential testing, and tailored testing. Adaptive testing might consist of the individual beginning with a moderately difficult question in the subtest. Then based on the response from that question, the individual is either asked an easier or more difficult question next. Computerized adaptive testing is also an option, and is meant to allow for the same type of tailored testing (Cohen and Swerdlik, 2010).

Adaptive testing is designed to guarantee that the initial questions in the test are at the correct difficulty level as to not dismay the individual for the rest of the questions. There are many other advantages of beginning the test with moderate difficulty, including decreasing the chance of the individual becoming frustrated during the test allows the administrator to gather more information in a more time-efficient manner, as well as building rapport with the test taker (Cohen and Swerdlik, 2010).

Once rapport is built between the individual and the administrator an item from a routing test is implemented. A routing test is used to direct the administrator to the certain level of questions. This is used in order to ensure the individual is answering questions at the correct level of difficulty. The two routing tests that are included within the SB5 include the Nonverbal Fluid Reasoning and Verbal Knowledge subtests, which are also the only two subtests used during the Abbreviated Battery IQ test (Cohen and Swerdlik, 2010).

There are three books that contain all of the questions and items from the SB5. The first two routing subtests are contained in book 1. Once the items from book 1 are completed, the administrator decides the appropriate place to start in the rest of the books. Book 2 contains four nonverbal subtests, labeled Knowledge, Visual-Spatial Reasoning, Quantitative Reasoning, and Working Memory. The last book contains four verbal subtests, labeled Fluid Reasoning, Visual-Spatial Processing, Quantitative Reasoning, and Working Memory. Some of the non-verbal and verbal subtests share the same names; nevertheless, they consist of different questions and tasks. For instance, the verbal subtest in Working Memory asks the individual to answer questions in which memory of an entire sentence is recalled verbally. However, the non-verbal subtest for Working Memory consists of the

individual completing tasks that resemble the shell game, in which they are to remember under which cup the shell is placed (Cohen and Swerdlik, 2010).

There are specific instructions included with the SB5 on where to start, reverse, and/or discontinue when administering the test. All examiners are trained in these rules and are required to follow them when conducting the exam. For example, the individual starts at their presumed ability level. Then, if the test taker receives a 0 for the first two questions, the administrator may decide to reverse the direction in which they are asking the questions to test using the correct difficulty level. If the test taker continues to receive scores of 0, the examiner may decide to discontinue testing. There are also guidelines to follow regarding prompting test takers. Specifically, if the individual answers questions vaguely the administrator is allowed to provide the prompt "Tell me more." Furthermore, in order to accommodate all prospective test takers, the majority of the questions on the SB5 are untimed (Cohen and Swerdlik, 2010).

Scoring and Interpretation

There are specific instructions on how to administer, score, and interpret the SB5 included in the test manual, as well as possible correct or incorrect answers for scoring the questions. Subtest scores are established by tallying scores of the individual questions within each subtest. The administrator then takes those raw subtest scores and creates a table to establish them into a standard score. Those standard scores are then used to determine the composite scores (Cohen and Swerdlik, 2010).

When a skilled administrator scores the SB5 more than the Full Scale IQ score and composite scores can be discovered. The test may also reveal some individual strengths and weaknesses about the test taker. Academic and clinical professionals can then use these findings to improve the individual's quality of life. (Cohen and Swerdlik, 2010)

There have been multiple types of analysis used to interpret scores in major cognitive ability tests. The commonality between those methods tends to be the recognition of differences between all scores, as well as the investigation of the factors that analyze the differences between them. In order to identify these important distinctions, the administrator must rely on normative data provided in the test manual as well as statistical calculations. When analyzing the scores the administrator may rely on the SB5 Technical Manual, which contains multiple tables for such help (Cohen and Swerdlik, 2010).

The SB5 not only allows for formal scoring, but it also allows for the administrator to make behavioral observation of the individual. Specifically, the administrator is trained to be aware of the test takers' "extra-test behavior." This may be defined as the way in which an individual copes with test frustration, how they react to seemingly easy tasks, how much support they need throughout, their approach to completing the task, and/or how fatigued, anxious, distractible, co-operative, or compulsive they seem to be. These types of behavioral observations are noted by the administrator using a questionnaire and affect the individual's formal score. Furthermore, the test also provides a space to record the individual's mood, activity level, current medications, physical appearance, and other related factors. Administrators are also encouraged to record any unusual observations during the test, as this may provide insight into further delays or deficits (Cohen and Swerdlik, 2010).

It is custom to convert the Stanford-Binet Full Scale IQ scores into nominal categories for quick reference and to allow for easier understanding for the general public. The categories have had many names throughout the years. However, the following are the SB5's cutoff boundaries and nominal categories:

Measured IQ range	Category
145–160	Very gifted or highly advanced
130–144	Gifted or very advanced
120–129	Superior
110–119	High average
90–109	Average
80–89	Low average
70–79	Borderline impaired or delayed
55–69	Mildly impaired or delayed
40–54	Moderately impaired or delayed

These categories, however, should only be used in reference. In order to prevent discrimination and/or labeling an individual into a "category," administrators and clinicians are encouraged to refer to the individual's abilities and skills in detail when referring to their SB5 test scores (Cohen and Swerdlik, 2010).

Introduction

The Wechsler Adult Intelligence Scale – Fourth Edition (WAIS-IV) is a comprehensive clinical instrument for assessing the intellectual abilities of older adolescents and adults. It follows a long tradition of development, testing, and improvement in the testing of mental abilities. Below is a review of the historical context that produced the modern intelligence assessment movement, the development and features of the WAIS-IV, and areas in which it is of most use clinically.

Historical Approach

The assessment of mental abilities began as a movement in the late nineteenth century, spearheaded initially by English statistician Sir Francis Galton (1869, 1883). Specifically, Galton believed intelligence to be a quantifiable construct through measurement of individual sensory and motor functions such as visual acuity, reaction time, and manual grip strength. More contemporary intelligence tests first appeared through the work of Alfred Binet and Theodore Simon, who were commissioned by the French government in 1894 to develop an objective method of distinguishing between normal and intellectually challenged children. Their subsequent 1905 Binet-Simon intelligence scale enjoyed wide use (Binet & Simon, 1905, 1908; Binet, 1911), and was soon thereafter adapted for use in the United States by Stanford professor Lewis Terman (Terman & Childs, 1912; Terman, 1916). His resulting Stanford-Binet scale was normatively based on a representative sample of 1,000 children and adolescents under the age of 14. Terman expanded the mental age categories first used in the Binet-Simon, to include adults based on a frequency distribution of 30 businessmen and 32 high school students.

As the United States entered the World War I in 1917, adult intelligence testing became an important tool in the assessment of draftees. American psychologist Robert Yerkes was charged with the task of developing psychometric tools to assign recruits to various levels of military service, a charge that resulted in the Army Alpha and Army Beta group-based tests. Guided by Binet's conceptualization of mental faculties and Yerkes' advocacy for *point scale* measures (i.e. functions that would not be expected to change significantly with age; Yerkes, 1917), the Army Alpha was intended for individuals with proficiency in reading/writing in English whereas the Army Beta was intended as a non-verbal supplement. The collective efforts of Binet, Simon, Terman, and Yerkes ultimately formed the basis for the modern intelligence test series, developed by Jewish American psychologist David Wechsler. Using the clinical skills and statistical training acquired as a mentee of statistician Charles Spearman and as a World War I psychology examiner, Wechsler constructed a series of intelligence tests that would overtake all others to become the most popular and widely used measures for decades to come.

Modern Approach

David Wechsler's motivation in constructing his intelligence scale differed from that of his predecessors. Whereas others valued intelligence tests for their utility in identifying the "feeble-minded" or predicting academic or occupational achievement, for Wechsler, an intelligence scale was a clinical instrument that would peer into the inner workings of the mind. Although he understood it as a global construct, Wechsler believed intelligence to include multiple, specific, and interrelated elements that could be individually measured. Even beyond World War I, Wechsler saw value in the continued development and refinement of intelligence tests appropriate for assessing adults and older adolescents.

Wechsler's conceptualization of intelligence was reflected in his first intelligence scale, the Wechsler-Bellevue Intelligence Scale (Wechsler, 1939). Published by the Psychological Corporation, the Wechsler-Bellevue provided a global composite intellectual score. It also provided verbal and non-verbal intellectual scores based on individual performance across 11 subtests adapted from the Stanford-Binet and Army series tests (i.e. Information, Comprehension, Arithmetic, Similarities, Digit Span, Vocabulary, Digit Symbol, Picture Completion, Block Design, Picture Arrangement, and Object Assembly). Importantly, Wechsler acknowledged that this verbal/non-verbal dichotomy was but one of many potential means in which intellectual domains could be feasibly organized. Nonetheless, the Wechsler-Bellevue was considered innovative due to its use of calculated standard scores based on deviation quotients derived from one's performance relative to a population-based average. This approach represented a significant point of departure and psychometric improvement upon Terman's calculation of IQ by dividing mental age by chronological age.

Released in 1955, the first Wechsler Adult Intelligence Scale (WAIS) represented a significant revision of the original Wechsler-Bellevue. It now specified Full Scale IQ, Verbal IQ, and Performance IQ indexes. Perhaps most importantly, the WAIS derived norms from a nationally stratified sample based on U.S. Census Bureau data, which was an improvement over its predecessor's small and geographically limited standardization sample.

Subsequent revisions were released in 1981 (Wechsler Adult Intelligence Scale-Revised; WAIS-R) and 1997 (Wechsler Adult Intelligence Scale-Third Edition; WAIS-III), which included revisions to test instructions, scoring rules, and the subtests themselves. Normative data were also more carefully stratified. New index scores were released, representing fluid-intellectual domains of working memory and processing speed. However, the most ambitious revision of the WAIS was still to come.

Wechsler Adult Intelligence Scale-Fourth Edition (WAIS-IV)

The Wechsler Adult Intelligence Scale-Fourth Edition (WAIS-IV; Wechsler, 2008) was released in 2008. Together, the 10 core subtests of the four index scales constitute the WAIS-IV Full Scale. Full Scale performance can be summarized using a composite score, the Full Scale IQ, as a measure of overall cognitive ability (FSIQ; Wechsler, 2008). FSIQ is composed of four indexes: the Verbal Comprehension Index, the Perceptual Reasoning Index, the Working Memory Index, and the Processing Speed Index (standard scores: mean=100, standard deviation=15) that are all based on a number of core and supplemental subtests (scaled scores: mean=15, standard deviation=3) that provide pertinent clinical information and flexibility in implementation. This WAIS revision offered multiple benefits over its predecessors, including revised instructions and improved floor/ceiling scores for reduced testing time, redesigned record forms for ease of use, subtest changes to reduce burden on motor demands, enlarged visual stimuli, and increased portability (Wechsler, 2008).

Primary and Supplementary Indexes

The WAIS-IV Verbal Comprehension Index (VCI; Wechsler, 2008) includes subtests that measure verbal abilities including expression of lexical and semantic knowledge, concept formation, abstract reasoning, and problem solving. WAIS-IV VCI is composed of three core subtests: *Similarities* (i.e. concept formation and abstract reasoning for pairs of related words), *Vocabulary* (i.e. lexical knowledge and expressive vocabulary), and *Information* (i.e. degree of general semantic knowledge). There is also one supplemental subtest that is optional in the WAIS-IV administration, *Comprehension* (i.e. practical knowledge and judgment using knowledge of abstract social conventions and rules).

The Perceptual Reasoning Index (PRI; Wechsler, 2008) includes subtests that measure non-verbal perception, organization, manipulation, and reasoning. WAIS-IV PRI is composed of three core subtests: *Block Design* (i.e. three-dimensional praxis, problem solving), *Matrix Reasoning* (i.e. pattern recognition, non-verbal abstract problem solving, inductive spatial reasoning), and *Visual Puzzles* (i.e. spatial rotation, reasoning, and non-verbal abstract problem solving). There are two supplemental subtests, including *Figure Weights* (i.e. quantitative and analogical reasoning) and *Picture Completion* (i.e. visual perception, recognition, organization).

The Working Memory Index (WMI; Wechsler, 2008) is composed of subtests that assess simultaneous and sequential processing, attention, and concentration. WAIS-IV WMI includes two core subtests: *Digit Span* (i.e. auditory processing, attention/concentration,

mental manipulation) and *Arithmetic* (i.e. attention/concentration, mental calculation, numerical reasoning). It also includes one supplemental subtest, *Letter-Number Sequencing* (i.e. sequential processing, mental manipulation, attention/concentration). The Processing Speed Index (PSI; Wechsler, 2008) includes subtests the measure the speed of mental and graphomotor processing. WAIS-IV PSI includes two core subtests: *Symbol Search* (i.e. visuoperceptual speed, visuomotor coordination, visual scanning, visual working memory, decision-making) and *Coding* (i.e. visuoperceptual speed, visuomotor coordination, visual working memory). There is also one supplemental subtest, *Cancellation* (i.e. visuoperceptual speed).

One concern regarding the WAIS has been the role of neuropsychological deficits in the reliability and validity of index scores, as neurologically compromised populations are more likely to display fluid impairments which may mask differences between general cognitive ability and other functions. To address this concern, the WAIS-IV included two optional composite scores. The first score serves to summarize general intellectual ability by eliminating working memory and processing speed performances from consideration (i.e. General Ability Index or GAI; Wechsler, 2008). Conversely, test users also have the option of a composite score that allows the user to distinguish fluid-intellectual from crystallized-intellectual abilities (i.e. Cognitive Proficiency Index or CPI; Wechsler, 2008).

Psychometric Properties

The WAIS-IV was standardized using a national sample representative of the U.S. English-speaking population aged 16 years 0 months to 90 years 11 months. Data were collected from March 2007 to April 2008. Stratified sampling was utilized to ensure representation of selected demographic variables based on U.S. Census Bureau data from 2005. Demographic variables of interest included age, sex, race/ethnicity, education level, parent education level, and geographic location. Amongst those excluded were individuals with physical or psychiatric conditions that might affect performance (e.g. traumatic brain injury, dementia, mood disorder, substance abuse/dependence) and individuals currently taking medication that might impact performance (e.g. anticonvulsants, antipsychotics).

The WAIS-IV normative sample was divided into 13 age groups: 16:0–17:11, 18:0–19:11, 20:0–24:11, 25:0–29:11, 30:00–34:11, 35:0–44:11, 45:0–54:11, 55:0–64:11, 65:0–69:11, 70:0–74:11, 75:0–79:11, 80:0–84:11, 85:0–90:11. The nine younger age groups contained 200 participants each, while the four older age groups contained 100 participants each. An equal number of males and females were contained in each age group, with the exception of the five older age groups, which each contained more women than men. The proportion of Whites, African Americans, Hispanics, Asians, and other racial groups in each age group reflected the U.S. population. Five education levels were defined: <=8 years, 9–11 years, 12 years, 13–15 years, and >= 16 years. Parent education was used for examinees aged 16 to 19. The four major geographic regions of the U.S. (i.e. Northeast, Midwest, South, West) were represented.

WAIS-IV reliability properties are reviewed within the user manual (Wechsler, 2008). Split-half reliability is generally strong for both FSIQ (i.e. ranging from .97 to .98 across the

13 normative age groups) and primary indexes (i.e. VCI = .96, PRI= .95, WMI=.94, PSI=.90), and ranges from adequate to strong across core and supplemental subtests (i.e. overall core subtest median of .89; overall supplemental subtest median of .87). Test-retest coefficients are also strong for the FSIQ (i.e. r=.96 across test-retest intervals ranging from 8 to 82 days) and primary indexes (i.e. VCI= .96, PRI=.87, WMI=.88, PSI=.87), and for subtests range from as high as .90 (Information) to .74 (Matrix Reasoning). Inter-rater reliability coefficients are similarly strong, ranging from .98 to .99 across all subtests – even in subtests with greater inherent subjectivity in scoring (i.e. Similarities=.93, Information=.97, Vocabulary=.95, and Comprehension=.91).

WAIS-IV validity properties are likewise reviewed within the user manual (Wechsler, 2008). Multiple confirmatory factor analysis studies support the four-factor structure of the WAIS-IV. Construct, structural, and incremental validity have been established for the primary indexes though subtest validity is less strong (Nelson, Canivez, & Watkins, 2013; Wechsler, 2008). Evidence of convergent and discriminant validity for the WAIS-IV has also been established via correlational studies with the WAIS-III, Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV), Wechsler Memory Scale-III (WMS-III), Children's Memory Scale (CMS), Wechsler Individual Achievement Test-II (WIAT-II), Brown Attention-Deficit Disorder Scales (Brown ADD), Delis-Kaplan Executive Function System (D-KEFS), California Verbal Learning Test-Second Edition (CVLT-II), and Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) across clinical populations.

Clinical Indications and Considerations

The WAIS-IV plays a central role in clinical practice. It has broad applicability to individuals aged 16–90 years, with a great deal of research describing patterns of cognitive performance across demographic, developmental, injury, and disease-related variables; normative data can be obtained for many clinical populations including those with intellectual disabilities, learning disorders, acquired brain injury, psychiatric disturbance, and neurodegenerative illness. Both normative and item-response data can also be utilized in the characterization of test performance and disambiguation of clinical diagnoses.

In 2009, Advanced Clinical Solutions (ACS; Pearson, 2009a, 2009b) was released as a supplement to the WAIS-IV and WMS-IV. ACS includes an assortment of additional scores, indexes, norms, and subtests that enhance and expand normative comparisons, assess functional status and social cognition, and detect suboptimal effort. The ACS Test of Premorbid Functioning (TOPF) is an additional valuable subtest that provides estimation of an individual's premorbid cognitive functioning, allowing for comparison with current functioning.

While WAIS-IV and ACS provide a wealth of information in and of themselves, clinicians should keep in mind that performance should always be interpreted in light of important contextual factors such as medical history, psychiatric history, psychosocial history, education, behavioral observations, previous testing performance, and the purpose of the evaluation. The complexity of the data obtained necessitates comprehensive training at the level of neuropsychologists, clinical psychologists, and school psychologists. One critical

consideration to the interpretation of WAIS-IV data is level of task engagement and effort (Boone, 2008). This determination should always be made on the basis of multiple sources of information and informed by objective measures of performance. WAIS-IV and ACS together include multiple embedded measures of performance validity (i.e. Reliable Digit Span, Word Choice subtest) that users can consider in light of base rates for normal, feigned impairment, and clinical populations.

Use of the WAIS-IV also requires clinicians to manage the test and the data obtained in an ethical manner. Clinicians should not base their assessment, interpretation, or recommendations on data that are outdated or inconsistent with the purpose of the measure. For example, using the most updated version of WAIS-IV with appropriate normative adjustments is critical for accurate and responsible assessment. Populations show gains in intelligence testing performance over time and, as such, intelligence tests must be standardized periodically to maintain accuracy (i.e. Flynn Effect; Flynn, 1987). On average, fluid intelligence testing performance increases by one standard deviation per generation, while performance on crystallized intelligence measures increases by less than a standard deviation. Increases have also been reported across other cognitive domains including semantic and episodic memory. It remains unclear what is driving the Flynn Effect, though some have hypothesized that literacy, testing familiarity, health, and environmental complexity could be contributing factors.

While our review relates only to the WAIS-IV and its contributions to intellectual assessment, we feel it important to note that development of the next revision is already well underway. Data collection for the WAIS-5 began in spring 2016 and is expected to end in spring 2020. Anticipated benefits include extensive updates to the normative sample, and opportunity for users to choose administration in either paper or digital formats. Until then, however, the WAIS-IV reigns as the most widely used intelligence assessment.

Wechsler Intelligence Scale for Children (WISC)

A. Alexander Beaujean and Nicole Woodhouse

Baylor University

The Wechsler scales have long history in the assessment of cognitive ability. The children's version of the scale, the Wechsler Intelligence Scale for Children (WISC), was published in 1949 as a downward extension of the Wechsler-Bellevue Form II. Since its original publication, it has undergone four revisions. The most recent edition is the fifth, which was published in 2014. Like its predecessors, the fifth edition of the WISC (WISC-V) is an individually administered, norm-referenced instrument, designed to assess both general and discrete domains of intelligence. Unlike previous editions, the WISC-V is available in traditional format as well as in the test publisher's *Q-interactive* format, which uses an iPad for administration.

Standardization

The normative sample for the WISC-V included 2,200 children between the ages of 6 to 16 years, with 100 males and 100 females at each of the 11 age levels. The sample was stratified according to the 2012 U.S. census to achieve proportional representation across age, sex, race/ethnicity, parent-education level, and geographic region. Additionally, the sample was selected to have a representative proportion of children with certain special education diagnoses (i.e. developmental delay, intellectual disability, specific learning disability, speech/language impairment, attention-deficit/hyperactivity disorder, gifted/talented).

Organization

The WISC-V has 21 subtests that assess intelligence in general, five of the most common specific intelligence domains (Verbal Comprehension, Visual Spatial, Fluid Reasoning, Working Memory, and Processing Speed), and some cognitive skills related to learning. The WISC-V authors removed two subtests from the previous edition (Word Reasoning and

Picture Completion), added three new intelligence subtests (Visual Puzzles, Figure Weights, and Picture Span) and five subtests measuring learning, and revised or created new items for all the remaining subtests. The WISC-V subtests are given in Table 1.

The subtests are classified using a three-level system. There are 10 primary subtests, six secondary subtests, and five complementary subtests. The primary subtests are those required for a comprehensive evaluation of intellectual ability. The secondary subtests supplement the primary subtests by measuring a broader sampling of intellectual functioning and provide additional information for clinical decision making. The complementary subtests were not designed to measure intelligence, *per se*; instead, they were designed to measure a variety of cognitive processes related to academic learning.

The raw scores from the subtests can be converted to age-based standard or scaled scores. In addition, a *processing score* can be calculated for most of the subtests. These scores are designed to provide more detailed information about the cognitive processes that contribute to an individual's performance on the subtests than raw or age-corrected scores.

There are 14 composite/index scores on the WISC-V, which are classified using a four-level system. There is only one score at the *Full Scale* level: the Full Scale IQ (FSIQ), which is designed to capture intelligence in general. It is composed of seven subtests. The five scores at the *Primary Index Scale* level were derived from factor analysis and are designed to measure the five common specific intelligence domains. At the *Ancillary Index* level, there are five scores that reflect various theoretical combinations of primary and secondary subtests. The *Complementary Index* level is composed of three scales derived solely from the complementary subtests.

Interpretation

The WISC-V authors' suggested interpretation of the test's scores is much more complex than previous editions. At the initial stage, they recommend interpreting norm-referenced scores for the FSIQ and other index scores, such as standard scores, percentile ranks, confidence intervals, and qualitative descriptors.

The remaining interpretation stages all involve intra-individual comparisons of subtest, index, or process scores. Although the WISC-V authors provided base rate information for the score differences, significance of these differences is determined using null hypothesis testing under the assumption that all scores for a given individual should be the same. There are two types of score comparisons, both of which are done to determine if an individual has any intra-individual cognitive strengths or weaknesses: comparing a score to either the mean of multiple scores or an index score (i.e. mean comparison), or directly comparing two scores (i.e. pairwise comparison).

Reliability

The WISC-V authors provided three types of reliability estimates: internal consistency (i.e. split-half correlations), inter-scorer agreement (i.e. comparing scores from two independent scorers of the same protocol), and stability (i.e. test-retest). Internal consistency

Table 1 Wechsler Intelligence Scale for Children-Fifth Edition Subtest Scores and Classifications

Subtest	Subtest Classification	Cognitive Domain	Full Scale	Primary	Ancillary	Complementary
Similarities	Primary	Verbal Comprehension	FSIQ	Verbal Comprehension	General Ability	
Vocabulary	Primary	Verbal Comprehension	FSIQ	Verbal Comprehension	General Ability	
Information	Secondary	Verbal Comprehension		Verbal Comprehension		
Comprehension	Secondary	Verbal Comprehension		Verbal Comprehension

Coding	Primary	Processing Speed	FSIQ	Processing Speed	Nonverbal; Cognitive Proficiency	
Symbol Search	Secondary	Processing Speed		Processing Speed	Cognitive Proficiency	

(*Continued*)

Table 1 (Continued)

Subtest	Subtest Classification	Cognitive Domain	Full Scale	Primary	Ancillary	Complementary
				Index Scores		
Cancellation	Secondary	Processing Speed		Processing Speed		
Naming Speed Literacy	Complementary	Learning				Naming Speed; Storage and Retrieval
Naming Speed Quantity	Complementary	Learning				Naming Speed; Storage and Retrieval
Immediate Symbol Translation	Complementary	Learning				Symbol Translation; Storage and Retrieval
Delayed Symbol Translation	Complementary	Learning				Symbol Translation; Storage and Retrieval
Recognition Symbol Translation	Complementary	Learning				Symbol Translation; Storage and Retrieval

estimates were estimated for all subtests except for those that have a speed element. For speeded tests, reliability was estimated using test-retest. Subtest and process score reliability estimates ranged from .80–.94 across all age groups; index score reliabilities ranged from .88–.96, with the FSIQ having the highest reliability. Inter-scorer agreement values ranged from .97–.99 for the 60 respondents for whom these values were calculated.

Stability estimates were calculated for 218 children with retest intervals ranging from nine to 82 days days. Uncorrected coefficients ranged from .63–.89 for the subtest and process scores, and ranged from .68–.91 for the index scores. Of note, the WISC-V authors did not report stability estimates of any inter-individual comparison scores.

Validity

The WISC-V authors provided validity evidence consistent with what was suggested in the third edition of the *Standards for Educational and Psychological Testing* (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1999). For content validity evidence, they reviewed the literature on the domains the WISC-V measure, hired expert consultants, examined item content, and directly questioned children about their understanding of items in some subtests.

For construct validity evidence, the WISC-V authors reported conducting a series of confirmatory factor analyses (CFA) as well as examining zero-order correlations of subtest, process, and index scores (i.e. multitrait-multimethod). For both methods, they reported finding evidence that the subtests measured their intended constructs.

For criterion validity evidence, the WISC-V authors reported two types of evidence. First, they reported correlations between scores on the WISC-V and scores from other instruments for non-clinical subsamples of the norming group. They gathered data on measures of intelligence (four instruments), academic achievement (two instruments), adaptive behavior (one instrument), and child behavior (one instrument, parent report from an omnibus rating scale measuring: resiliency, conduct problems, executive functioning, and attention problems). The correlations with other intelligence measures were moderate to high for similar composite scores, with the highest correlations coming from the FSIQ (range: .77–.84). Likewise, comparisons between the academic achievement composite scores and the WISC-V FSIQ were generally higher than those from other WISC-V scores (range: .49 –.81). Most of the correlations between the WISC-V scores and measures on both the adaptive behavior and child behavior scales were low. They interpreted this as indicating the WISC-V scores had divergent validity because the WISC-V was not designed to measure adaptive behavior or general child behavior.

The second type of criterion validity evidence reported is mean differences in WISC-V scores between convenience samples of "special groups" of children (i.e. gifted, intellectual disability, borderline intellectual functioning, specific learning disorder, attention-deficit/hyperactivity disorder, disruptive behavior disorder, traumatic brain injury, and English-language learner) and matched individuals in the norming sample. The mean differences were generally in the areas thought to be affected by the nature of the special groups' diagnosis. The WISC-V authors concluded that these differences provide strong support for the validity and clinical utility of the WISC-V.

Critique

Since the WISC-V was published recently, there have been very few third-party publications empirically examining the scores or reviewing the instrument. Canivez and Watkins (2016) likely provided the most thorough critique of the instrument to date. Not only did they review all the WISC-V materials and manuals, but they also re-analyzed the summary data therein.

They commended the WISC-V authors for using a large, demographically representative standardization sample, taking many steps to make the administration better than in previous editions, and adding two measures of Fluid Reasoning – an area that was not measured well in previous editions. Moreover, they praised the WISC-V authors for providing many correlation matrices and descriptive statistics so that independent researchers can study various aspects of the WISC-V.

Canivez and Watkins' (2016) criticisms of the WISC-V are manifold, but some of their most cogent ones are:

- *Selective literature review.* The technical manual does not discuss any of the problems involved with inter-individual score comparisons. This selective reporting is particularly troubling given the corpus of literature in this area.
- *CFA methods.* The CFA methods reported in the technical manual are not very transparent. First, the authors did not fully describe their model specification, so Canivez and Watkins could not reproduce the technical manual's results. Second, the authors selectively interpreted the CFA fit measures to highlight their preferred model (i.e. one general factor and five group/specific factors). This selective interpretation could have resulted in selecting an over-factored model.
- *Lack of exploratory methods.* The authors did not report conducting any exploratory factor analyses despite the addition of new subtests, deletion of old subtests, and the revision of item in most subtests.
- *No evidence supporting reliability of non-general scores.* Given the WISC-V authors' emphasis on interpreting scores other than the FSIQ, they should have provided estimates of how much subtest variance is due to a general factor versus that due to the specific group factors. In Canivez and Watkins' reanalysis of the WISC-V summary data, they found that a general factor accounted for 35% of the subtests' total variance and 68% of the common variance. The group factors accounted for very little variance beyond the general factor. The Verbal Comprehension factor accounted for the most non-general variance, but even it was minimal: an additional 4% of the subtests' total variance and an additional 7% of the common variance. Thus, Canivez and Watkins questioned the wisdom of interpreting any score on the WISC-V except the FSIQ.

Wechsler Preschool and Primary Scale of Intelligence (WPPSI)

Jasmin Pizer[1] and Amanda ElBassiouny[2]

[1] *Spring Hill College*
[2] *California Lutheran University*

The Wechsler Preschool and Primary Scales of Intelligence (WPPSI) is a scale designed by psychologist David Wechsler, with the purpose of measuring children's intelligence at ages 2 years and 6 months to 7 years and 7 months. Wechsler has created many intelligence scales for different age groups, all of which have the same general structure and are meant to estimate dimensions of intelligence, along with overall intelligence. This scale has been adapted for use in countries around the world and, for English-speaking populations, is one of the most widely used scales to measure intellectual functioning. The reason it is so widely used is because this scale shows intelligence scores at multiple levels, including the primary factor-based composite index scores and the theoretically based ancillary index scores. Based on the scores for the subscales of intelligence and the composite score, clinicians are able to use it as a comprehensive neuropsychological assessment of cognitive and adaptive functioning in children (Thorndike, 2014). The most recent version of this intelligence scale is the Wechsler Preschool and Primary Scale of Intelligence-Fourth Edition (WPPSI-IV). The scale underwent some changes in order for updates to be made and concerns to be addressed. These changes included four subtests being removed, five being added, and modifications being made to the content, administration, and scoring. This was done in order to decrease redundancy, include measures for working memory and processing speed, and to create more engaging, child-friendly material (Canivez, 2014).

WPPSI-IV Mechanics

Even though the WPPSI-IV is used on children ages 2 years and 6 months to 7 years and 7 months, within this age bracket there are two separate age bands: (1) 2 years and 6 months to 3 years and 11 months and (2) 4 years to 7 years and 7 months. The scale uses different subsets for these two age bands because of the differences in development and cognition (Canivez, 2014). With the switch from the third edition to the fourth, four subtests were

removed, five were added, and modifications were made to the content, administration, and scoring. With these changes, the scale includes 15 subtests for each age band, but the subtests vary in content between the two age bands. The five subtests that were added were put in place to measure working memory and processing speed. The working memory subtests now use proactive interference and the processing speed subtests are now more game-like so that the children are easily engaged. For example, some child-friendly subtests that were added include Zoo Locations, Bug Search, and Animal Coding. An ink dauber is provided for children taking the test to mark answers so that they can do so quickly.

WPPSI-IV Scoring

Scores for the WPPSI-IV can be interpreted at three different levels. These levels include full scale, index scale, and individual subtests. Multiple subtest scores are combined to make up the primary, factor-based composite, index scores (Thorndike, 2014). These index scores represent intellectual functioning and cognitive ability. There are also ancillary index scores, which are supplemental and allow for broader sampling. The Full Scale IQ for the 2 years and 6 months to 3 years and 11 months age band consists of the Verbal Comprehension Index, Visual Spatial Index, and Working Memory Index. The primary index scales include the Verbal Comprehension Index, Visual Spatial Index, and the Working Memory Index. The Ancillary Index scales include the Vocabulary Acquisition Index, Nonverbal Index, and the General Ability Index. The Full Scale IQ for the 4 years to 7 years and 7 months age band includes the Verbal Comprehension Index, Visual Spatial Index, Fluid Reasoning Index, Working Memory Index, and the Processing Speed Index. The primary index scales consist of the Verbal Comprehension Index, Visual Spatial Index, Fluid Reasoning Index, Working Memory Index, and the Processing Speed Index. The Ancillary Index scales include the Vocabulary Acquisition Index, Nonverbal Index, General Ability Index, and the Cognitive Proficiency Index. Each index includes certain subtests. For example, the Cognitive Proficiency Index consists of the Picture Memory, Zoo Locations, Bug Search, Cancelation, and Animal Coding subtests. The Full Scale IQ score is always administered first.

Limitations and Current Usage

Although many changes were made when updating the Wechsler Preschool and Primary Scales of Intelligence from the third edition to the fourth edition, some limitations remain. The WPPSI-IV is in need of strong empirical evidence before being able to apply its results to individuals (Canivez, 2014). Also, the WPPSI-IV Technical and Interpretive Manual should have included more statistical analyses and results so that the full account of its accuracy could be evaluated. Because of this, clinicians must wait for new studies to emerge before judging whether the WPPSI-IV should be used or not.

Intelligence-Personality Association, Assessment of

Larissa-Jayne Edwards and Ingrid K. Weigold

The University of Akron

Intelligence and personality are two of the main constructs examined in individual differences research (Chamorro-Premuzic & Furnham, 2006). Intelligence, in particular, has held a prominent stance in behavioral science research, with individual differences researchers largely in agreement on both the psychometric properties of intelligence and methods of measurement (von Stumm, Chamorro-Premuzic, & Ackerman, 2011). There is less agreement regarding personality, with researchers continuing to determine its properties. Additionally, the main method of capturing personality data is via self-report measures, which access only explicit personality (known by the subject) and neglect implicit personality. The current understanding of the association between intelligence and personality is even less clear. Currently, no standardized assessment battery is in use that has the sole intention of singlehandedly capturing intelligence-personality associations. Rather, separate assessment measures are used to record intelligence and personality data independently, and statistical tests are then utilized to determine their relationships.

The assessment of intelligence-personality associations is shaped by a study's demands and intentions. Although intelligence and personality share many similarities that should assist in understanding their relationship to each other, such as showing temporal stability and having genetic components (von Stumm et al., 2011), it is their differences that tend to complicate the understanding of how the two constructs are related. There are currently only three theoretical perspectives on intelligence-personality associations present in the individual differences literature (von Stumm et al., 2011). As a result, the assessment of intelligence-personality association remains largely experimental.

The first theory of intelligence-personality associations, originally developed by Edward Webb in 1915, posits that intelligence and personality are independent of one another (Webb, 1915, as cited by von Stumm et al., 2011). Historically, research has generally found low correlations between intelligence and personality, as well as their conceptual features (von Stumm et al., 2011). This track record has slowed down the drive for research on intelligence-personality associations in the past. More recently, however, researchers have

argued for continuing to examine their association, stating that the correlations between intelligence and personality are modest, indicating the presence of *some* relationship, and that studying these constructs in relation to each other may serve to increase the understanding of both (von Stumm et al., 2011). For example, measures of intelligence have frequently been shown to predict academic achievement; however, this has not been the case for personality measures (Chamorro-Premuzic & Furnham, 2006). This lack of prediction of academic ability from personality measures may be linked to the demands of the educational setting (von Stumm et al., 2011). When demands are basic at lower educational levels, personality does not appear to play as great a role. When the demands are greater, such as in postsecondary educational settings, personality has a larger impact in determining educational qualification, persistence, and work performance and attendance.

A second theory of intelligence-personality associations, presented by Furnham, Forde, and Cotter in 1998, posits that there are relationships present at the measurement level (von Stumm et al., 2011). These associations specifically address the impact of personality on intelligence test performance, not ability, indicating that personality affects the measurement of intelligence. The traits of extraversion and neuroticism have played a central role in these particular associations.

As originally discussed by Eysenck, extraversion and introversion have been found to have a connection to cortical arousal and arousability, wherein extraverts have comparatively lower levels of both and introverts have higher levels (Eysenck, 1957, as cited by von Stumm et al., 2011). When considered within the parameters of the Yerkes-Dodson law, which states that moderate levels of arousal lead to greater performance than either high or low levels, these differences in arousability may have a role in intelligence test performance (von Stumm et al., 2011). Research on this topic has yielded inconclusive findings. For instance, it has been shown that introverts perform better in silence than either extraverts or ambiverts, whereas extraverts do better with auditory stimulation (Bates & Rock, 2004). However, other researchers have failed to find similar results, leading some to propose that there are moderating variables in the relationship between intelligence and extraversion, such as the measures used (Wolf & Ackerman, 2005).

Neuroticism and intelligence have consistently been shown to be negatively correlated (von Stumm et al., 2011). Scholars have posited that this relationship is due to the negative impact of the primary facets of neuroticism, such as anxiety and frustration, on the test performance of individuals high in neuroticism (Furnham et al., 1998). Consequently, the components of neuroticism may influence a test-taker's ability to focus. Research has supported this assertion, finding that test anxiety is positively related to both state and trait anxiety, as well as decreases in performance on intelligence tests (Hembree, 1988). Further research has determined that test anxiety relates to the latent trait of general ability (Reeve & Bonaccio, 2008).

The third theory of intelligence-personality associations consists of a developmental relationship between intelligence and personality, which states that personality traits influence individuals' specific applications of their intelligence (Chamorro-Premuzic & Furnham, 2006). These conceptual associations have been considered within the frameworks of three theories: (1) investment, a model concerned with diminishing returns and age-related performance, which was initiated by Cattell in the 1940s and more fully

developed by Ackerman in 1996; (2) compensation, a model developed in 2005 by Chamorro-Premuzic and Furnham that examines how personality and related traits may be used to offset differences in intelligence; and (3) differentiation, a model based on Spearman's 1927 law of diminishing returns in which intellectual development splits off from cognitive abilities (Ackerman, 1996, Cattell, 1943, Spearman, 1927, as cited by von Stumm et al., 2011; Chamorro-Premuzic & Furnham, 2005).

Investment theory has its roots in Cattell's proposal of intelligence as having both a fluid nature and a crystallized counterpart in that there are individual differences in the tendencies to partake in activities that encourage learning, including age and return expectation (von Stumm et al., 2011). Expanding upon this, investment traits influence seeking out and engaging in cognitive activity (von Stumm, 2010). The personality construct openness to experience has been hypothesized as being such a trait, and research has confirmed a significant relationship between openness to experience and intelligence (von Stumm et al., 2011).

Compensation focuses on the trait of conscientiousness. Although intelligence and conscientiousness have been shown to be independent of one another, some studies have found small negative correlations (von Stumm et al., 2011). Researchers have suggested that conscientiousness may serve as a compensatory mechanism for those with lower levels of intelligence but may not be needed to the same degree by those with higher levels. Although preliminary research has found support for this relationship between conscientiousness and intelligence (Postlethwaite, Robins, Rickerson, & McKinniss, 2009), there is a current need for it to be explored within various settings (von Stumm et al., 2011).

Differentiation is a model based on Spearman's law of diminishing returns (von Stumm et al., 2011). This law states that the higher an individual's level of *g*, the smaller the variance in ability test scores that can be ascribed to *g*. Building off this idea, Garrett (1946) proposed that general ability transforms into separate aptitudes as one ages, which is known as age differentiation (see von Stumm et al., 2011). Personality differentiation has focused on the study of neuroticism, with Eysenck and White hypothesizing that, as neuroticism increases, intelligence differentiation decreases (Eysenck & White, 1964, as cited by von Stumm et al., 2011). Results for this suggestion have been inconsistent, and further research examining both neuroticism and other personality traits is warranted (von Stumm et al., 2011). The study of personality on intelligence differentiation stems from the theory that, as *g* increases, so do the person's separate personality facets. Higher levels of *g* promote the development of more, or more differentiated, personality factors. However, there have been few previous efforts to research intelligence differentiation, and available studies have yielded inconsistent findings.

Although research has recently called for different ways of testing and identifying the relation between intelligence and personality, the tools used for measuring intelligence-personality associations have generally remained the same. Personality has been captured by measures such as the NEO Personality Inventory and the Minnesota Multiphasic Personality Inventory. However, recent research has suggested that there may be a general factor of personality, similar to the concept of *g* intelligence, which may have the potential to provide a more unified representation of personality and assist in comparisons to general intelligence (Dunkel, 2013). Intelligence has been measured by tests including the

California Achievement Test Battery, Raven's Progressive Matrices, and the General Ability Test Battery. Intelligence has also been separated into crystallized, fluid, visuospatial, and other subgroups, and specific tests capturing these different types have been utilized. There is no single test developed to measure intelligence-personality associations, and current practice for measuring intelligence-personality associations continues to be by measuring the two constructs separately.

Abilities, General Features and Methodological Issues

F. R. Ferraro

University of North Dakota

What are Cognitive Processes?

Although one can trace cognition back many centuries, more contemporary scholars see the 1940s–1960s as seminal decades with regard to cognition. Out of the ravages of World War II, theories, hypotheses and aspects of cognition and human information processing (HIP) started to emerge both in the United States and Britain. Arguably, Donald Broadbent's 1958 *Perception and Communication* and Neisser's 1967 *Cognitive Psychology* set the tone. Both covered much ground in their respective texts and areas of study in each are still empirically investigated to this day. For instance, Broadbent included chapters on individual differences and vigilance performance while Neisser included chapters on words as visual patterns and echoic memory and auditory attention. It is also important to know that the study and field of cognitive psychology as related to personality and individual differences are ever-expanding as evidenced by recent papers published in the journal *Personality and Individual Differences* (Carl, 2015; Shorey, Elmquist, Anderson & Stuart, 2015; Soboki & Zelinski, 2015).

A fundamental question facing psychologists at the time was how individuals process information. Do they do so via a typical stage theory, where one stage must finish before another stage can start? Or do they instead allow multiple processes to occur at the same time over a specific time period with no specific start and stop time for stage development and execution? While these models have evolved over the past 50–60 years, another fundamental requirement of cognitive processes is that they are internal mental representations of actions, events, and procedures. Their existence is assumed by changes or alterations in behavior although the exact process (or processes) is unseen and not observable. This key operation definition of cognitive processes will be taken up when I discuss the use of reaction time later in this entry.

How do Cognitive Processes relate to Abilities and General Features?

One hallmark of cognitive processes as detailed previously is that they are often used to define behavioral characteristics that relate to general ability. For instance, someone can be either fast or slow, loud or quiet, or correct or incorrect. These and other dimensional qualifiers allow for a continuum of ability level (good, poor) that often can be tied to underlying cognitive processes. In turn these can be related to issues in personality in the sense of someone who might be regarded as "impulsive" might therefore process information in a fast way, yet might also make many errors due to the quickness of their responses style. Likewise, someone who is socially withdrawn or shy may take longer to respond in social situations that rely on social contact and interaction. Why these individuals may be fast and inaccurate or socially withdrawn can be traced back to variations and aspects of their ability (or inability) to adequately process information.

How to study Cognitive Processes, Abilities and General Features

As mentioned above, one typical option in studying people of differing abilities is to quantify them along a continuum (fast-slow, good-poor, high-low, right-wrong). Often times this also involves some dimension of personality. And while many professional journals exist that document such empirical types of studies, *Personality and Individual Differences (PAID)* is arguably one of the best empirical journals in this regard. For instance, a recent issue of this journal included articles ranging in topics from hardiness and the Big Five Model (Costa & McCrae, 1992) to subclinical psychopathic subtypes to selfie posting behaviors and narcissism. Likewise, the various methodologies employed in these are other articles in this issue including the dot-probe task, the lateralized lexical decision task, thought suppression using rumination induction. As the aims and scope of this journal detail, PAID is devoted to the publication of articles which integrate the major factors of personality with empirical paradigms or to seek explanation for the cause(s) and major determinants of individual differences. Many papers that appear in this (and other) journals employ reaction time (RT) methodologies as a means to these ends.

To this end, a recent chapter by Robinson (2007) nicely shows how the use of RT to study cognitive processes at the millisecond (ms) level has wide appeal and applicability to the study of personality. He outlines three broad arguments as to why the millisecond timing approach that dominates cognitive psychology may be as or more appealing to those who study personality. These three approaches include the objective nature of measuring personality using RT; the observation that RT relationship to cognitive processing is able to assess and interpret behavior in real time; and the ability to assess and explore the dynamic aspect(s) of personality at the cognitive level. Despite these applications, Robinson (2007) is right to observe that cognition and information processing are dynamic and ever-changing while, for most of us, personality differs little across the lifespan. Nonetheless, RT and its use to identify the many underlying cognitive stages and processes and individual possesses are critical for a more well-defined definition of personality and its assessment.

The Case for Response Time/Reaction Time as a Methodological Issue

One way to examine the underlying (and unobservable) information processing stages and variables is to employ a reaction time (RT) paradigm. Studies of RT, and especially those that map out and identify the internal mental representations associated with cognitive psychology and information processing, are not new. In fact, one can examine the work of Donders (1869, 1969), who showed that by using the subtractive method one can examine the execution as well as the duration of mental processes. Recent examples of this subtractive methodology include simple reaction time (SRT), Go-NoGo Task, and choice reaction time (CRT) tasks. As the name implies, SRT is simply the time taken (usually measured in milliseconds, or thousands of a second) to respond to a stimulus (e.g. light, sound, touch). In the Go-NoGo task, subjects must respond to one specific stimulus (red light) while not responding to another specific stimulus (green light). Finally, CRT suggests that subjects made one response to one type of stimulus (press the M key when a word appears on a screen) and another response when a different stimulus appears (press the X key when a non-word appears on the screen). While Donders' approach was widely popular at the time, recent updates have concluded that specific stimuli can affect performance not only quantitatively (as Donders had speculated) but also qualitatively. Sternberg (1966) revised and refined Donders' work to accurately measure the times needed for executing various hidden mental processes and mental events. Cognitive psychologists now routinely measure these hidden internal mental representations using many of the RT paradigms listed above. Likewise, many types of psychologists also now routinely use RT to examine information processing abilities and deficits across a wide range of personality variables. In turn, it is now possible to make predictions about how information processing tasks using RT can tell us about the underlying mental events of a variety of personality-related subgroups as well as those with personality disorders.

Assessment of Antisocial Behavior

M. Justin Miller and Tiffany Smith

University of Wisconsin–Stout

Antisocial behavior is characterized by overt and intentional hostility and aggression toward others. This can debilitate an individual from functioning normally in society. The majority of research conducted on antisocial behavior assessment has focused on the prevention of criminal behavior. All too often, the characterization of antisocial behavior is presented in criminal behavior, which can prevent individuals from contributing normally to society and limit their future opportunities. Antisocial behavior tends to be prevalent in individuals that display certain degrees of personality traits. The degree of personality traits in which an individual is more likely to display in antisocial behavior has led to the identification of antisocial and narcissistic personality disorders. Although there are many personality traits to take into consideration in regard to personality disorders and antisocial behavior, personality traits that display malicious intent have attained a large amount of attention in research examining antisocial behavior. Malicious personality traits include sadism, Machiavellianism, narcissism, and psychoticism. Although each of these traits increases the likelihood that an individual will engage in antisocial behavior, psychoticism seems to be the most recognized trait. Psychoticism is defined as aggressiveness and interpersonal hostility that results in impulsivity, risk taking, and/or violent behaviors and actions. Before discussing further the assessment of antisocial behavior, it is important to understand the intellectual and social contexts of antisocial behavior development.

Theoretical and Social Contexts of Antisocial Behavior

There are three primary areas of psychological theories that link antisocial behavior to personality. The focuses behind these theoretical areas of personality regarding antisocial behavior include descriptive and exploratory factors, social conditions, and development. To begin, there are theories that focus heavily on the essentialness of personality traits for

understanding descriptive and explanatory factors of antisocial behavior. For instance, research utilizing the Five Factor Model has found that individuals who present antisocial behavior have the tendency to display higher levels of extraversion and neuroticism, as well as lower levels of agreeableness and conscientiousness.

Although some personality theories focus on general personality traits to describe antisocial behavior, other theories have focused on the interaction between less general personality traits and poor social predispositions that contribute to antisocial behavior. For example, research utilizing Eysenck's Psychoticism-Extraversion-Neuroticism (P-E-N) Model has shown that individuals that are high in extraversion, neuroticism, and psychoticism, and have experienced poor childhood and/or environmental conditions are more likely to commit crimes. Eysenck's P-E-N Model has been exceptionally useful for assessment because the model identifies a combination of personality factors that increase the likelihood of antisocial behavior. Eysenck created the P-E-N Model because the three factors in the model (psychoticism, extraversion, and neuroticism) display less overlap than the personality traits assessed in the Five Factor Model. In regard to antisocial behavior, Eysenck hypothesized that individuals would be at a greater risk of developing antisocial behavior if they scored high on all three P-E-N Model factors as well as low scores on the Lie Scale, a fourth component to Eysenck's Personality Questionnaire-Revised (EPQ-R) that is accompanied by scales for each of the P-E-N Model factors. Recent research has found that there was a significant difference between individuals that fit these criteria and those that do not.

Finally, developmental theories have suggested that dispositions toward maladaptive behavior and malicious personality traits presented early in life increase the likelihood of the individual engaging in antisocial behavior. Specifically, the general propensity theory has suggested that impulsive individuals will display low self-control early in life and are more likely to engage in antisocial behavior. On the other hand, the developmental trajectory theory emphasizes several factors that cause deviant behavior like poor social conditions such as poverty or familial distress. In consideration of poverty and poor household conditions, malnutrition can cause children to develop antisocial behavior that is debilitating without treatment. This can often grow more severe over time, especially if the malnutrition continues as a child is developing. There are a variety of other social conditions that have been linked to the development of antisocial behavior, aside from malnutrition. Other social conditions include lack of or poor social support networks, large amounts of distress, and trauma. Although developmental theories focus on the development of maladaptive behavior and malicious personality traits in childhood and adolescence, it is possible for antisocial behavior to develop in adulthood. However, this generally occurs because of traumatic brain injuries or neurological disorders that develop in adulthood.

Major Dimensions of Antisocial Behavior Assessment and Research

Although personality trait theories are important for understanding the psychological mechanisms that contribute to antisocial behavior, it is also clear that neurological assessment of antisocial behavior can be important for understanding this form of maladaptive

behavior. Historically, the literature on antisocial behavior presents cognitive factors that are related to behavior and personality change after brain lesions. For example, in the case study of Phineas Gage published in 1868, Gage displayed cognitive, behavioral, and personality dysfunctions after experiencing a brain lesion in the orbitofrontal cortex. Although this case study laid a foundation for neurological assessment of antisocial behavior many years ago, current research has placed emphasis on the use of modern medical equipment and technology to understand neurological mechanisms of antisocial behavior. These current neurological assessments have identified poor executive functioning as a major contributor to the increased likelihood of antisocial behavior. Generally, these assessments are used to determine intellectual and mental capacity in which low levels are related to identifying psychoticism, and therefore, antisocial behavior.

Although understanding the development and neurological mechanisms of antisocial behavior is important, being able to properly identify and assess antisocial behavior is necessary for providing treatment early on, which can make a huge difference in how the individual with antisocial behavior and the people around them are affected. Furthermore, these assessments and interventions can contribute to a decrease in criminal behavior which individuals with antisocial behavior are likely to engage in. Although experimental research and neurological assessments focus on the causes of antisocial behavior, assessments of personality typically focus on psychoticism and other malicious personality traits (such as sadism, Machiavellianism, narcissism) to predict antisocial behavior.

There are a variety of measures used to assess and predict antisocial behaviors. The Elemental Psychopathy Assessment is used to examine maladaptive variations of personality traits from the Five Factor Model that are related to psychopathy. However, one of the more popular scales used to assess psychopathy in relation to antisocial behavior is the psychoticism subscale of the EPQ-R. EPQ-R assesses the traits described in Eysenck's P-E-N Model as well as a subscale to assess lying. Another commonly used measure to assess malicious personality traits is the Dirty Dozen. This measure is used to assess the Dark Triad personality traits, which include Machiavellianism, narcissism, and psychopathy. Although the Dirty Dozen has been a popular measure for measuring Dark Triad personality traits, the new Short Dark Triad measure is becoming a more popular way to assess the Dark Triad personality traits. The Short Dark Triad measure was constructed in 2014 to provide a faster way of measuring these traits without being too short, like the Dirty Dozen which only consists of 12 items. With the Short Dark Triad, both Machiavellianism and narcissism are assessed with nine items per construct and psychopathy is measured with six items, whereas each trait is only measured with four items per construct in the Dirty Dozen.

Although measures focusing on an array of malicious personality traits can be useful for assessing and identifying individuals likely to engage in antisocial behavior, many of these traits can also be assessed with individual measures. For instance, Machiavellianism had been measured using the Mach IV Inventory for decades until the Machiavellianism Personality Scale was developed in 2009. Narcissism is typically assessed by using the Narcissistic Personality Inventory. However, some recent research has used the newly constructed Five Factor Narcissism Personality Inventory to assess narcissism. Psychopathy/Psychoticism has been assessed using the Elemental Psychopathy Assessment and the Psychoticism subscale of EPQ-R. Finally, sadism has been assessed using the Short Sadistic Impulse Scale and the Varieties of Sadistic Tendencies measure.

Future Directions of Antisocial Behavior Assessment and Research

Although there are many ways to assess antisocial behavior, there is still more to be done. One primary emphasis in antisocial behavior assessment currently is the developmental contributions to antisocial behavior. Research on this topic has turned its focus on longitudinal data to identify social, biological, and environmental factors that influence antisocial behavior. Future research in this area should also focus on pregnant women to understand how habits and activities during pregnancy influence developmental outcomes during early childhood and adolescence. In regard to the need of understanding the developmental outcomes of children, longitudinal research is important for identifying changes over time in individuals prone to antisocial social behavior.

Although emphasis for future research has primarily indicated the need for longitudinal data, some recent cross-sectional research has focused on the identification of environmental and social setting factors (such as location of residence, familial income levels, and social interactions) to determine if differences between groups influence antisocial behavior. As an example, research has shown that individuals that are in hostile familial settings and/or poor living conditions tend to be more likely to engage in antisocial behavior than individuals not in these conditions. However, another major area of future research that has been pointed out by major contributors to research on antisocial behavior is intergenerational studies. Not only should this integration take place between generations through cross-sectional research, but antisocial behavior should also be assessed through an integration of longitudinal research examining biopsychosocial development, community factors, and environmental factors. Longitudinal studies are highly suggested in current research to fully understand these integrations of factors that contribute to antisocial behavior over time.

Although a vast amount of research indicates a need for longitudinal developmental studies, neurological assessment of antisocial behavior is important to identify genetic predispositions to antisocial behavior. As technological advances continue and research becomes more complex, the use of neurological assessments has the potential to reveal neural and genetic mechanisms of antisocial behavior. By examining genes of individuals in early childhood, longitudinal research can examine if any of these genetic factors seems to produce individuals that engage in antisocial behavior. Longitudinal research is not only important for identifying antisocial behavior, but also to specifically identify developmental changes that may influence the likelihood of an individual engaging in specific antisocial behaviors, such as criminal behavior. Making these identifications can allow future researchers to design interventions and procedures that can decrease the likelihood of an individual engaging in antisocial behavior.

In regard to identifying factors of influence for antisocial behavior, a massive effort regarding personality factors in this area of study should be to identify and assess individuals likely to engage in criminal antisocial behavior. Since antisocial behaviors are linked to criminality, this area of focus is important to reduce criminal behavior and provide interventions for those that have committed criminal acts. As mentioned earlier, individuals that are high in extraversion, neuroticism, psychoticism, aggression, and hostility, as well

as low in agreeableness and conscientiousness, maintain a high likelihood of engaging in antisocial behavior that can lead to them committing criminal acts. However, research has also identified other personality characteristics that influence criminal antisocial behavior. These characteristics include lack of self-control and high levels of sensation seeking and impulsivity. As scales of measurement continue to become more complex and reliable, it is very important to examine antisocial behavior from a personality perspective to create treatments and interventions that can change these personality factors.

Career and Vocational Interests and Abilities, Assessment of

Dong Xie and Cory L. Cobb

University of Central Arkansas

Conceptualizations

Assessment of career and vocational interests and abilities is an essential activity in career counseling and vocational development. The purpose of assessing career interests and abilities is to facilitate self-exploration and self-understanding with respect to one's interests, abilities, or perceptions of one's abilities. These assessments help people gain self-knowledge, generate career choices, and make effective career decisions.

A Brief History of Career Assessment

Career assessment has been in practice since the 1900s when Frank Parsons developed the first framework of career guidance. According to Parsons, career guidance involves three basic steps: (1) a clear understanding of oneself, one's interests, aptitudes, abilities, ambitions, resources, and limitations, (2) knowledge of the requirements and conditions in different lines of work, and (3) the true reasoning on the relations of these two groups of facts. Parsons was among the first proponents of using career assessment for the purpose of clearly understanding the person. Parsons's framework has served as the foundation for the trait-and-favor theories in career counseling and development, which are fundamental in guiding the development and use of many career assessment inventories including assessment of career interests and abilities.

Interests and Abilities

Interest is one of the most frequently assessed attributes in career counseling and career assessment. Interests can be classified as expressed interests, manifest interests, and inventoried interests. Expressed interests are the activities that individuals state they like to do.

Manifest interests refer to the activities that they are actually spending time on. Inventoried interests can be identified through interests inventories, such as those introduced in this entry.

Ability is another important attribute frequently measured in career assessment. Ability is closely related to two other attributes, aptitude and achievement, but a conceptual distinction among them is necessary. Achievement can be understood as something that the individual *has already learned* or *achieved*. While aptitude reveals the potential level of ability with which one may perform well on a task in the *future*, ability refers to the level of *present* ability as demonstrated by one's current performance on a task. Self-perception of ability is often conceptualized as self-efficacy in career counseling and development. Self-efficacy, a key concept in social cognitive career theory, is defined as one's confidence of one's ability to organize and take action to attain certain career goals. Self-efficacy, though a relatively new construct in career development, has been intensively studied and has been demonstrated to impact career choices, career decision-makings, and attainment of career goals.

It should be noted that interest, actual level of ability, and self-efficacy are all related but different constructs. Research has found a small but significant correlation between interest and self-efficacy. One may be interested in doing something but may not feel confident in such an activity, and vice versa. Similarly, one's actual level of ability in doing something might be high, but one may or may not be interested in the activity and may or may not feel confident in performing such an activity. Therefore, it is important that all of these attributes, together with many others, should be evaluated and considered in generating career choices and making career decisions.

Assessment of Career and Vocational Interests

Theoretical Framework

Expressed interests and manifested interests can be assessed through qualitative approaches such as interview or observation. However, in the context of career and occupational development, interests are most often assessed by career interest inventories. Many of the interests used in career counseling are based on John Holland's trait-factor model and in these inventories, career interests are largely an expression of one's personality type.

According to Holland, people and work environments can be classified as six types: Realistic (R), Investigative (I), Artistic (A), Social (S), Enterprising (E), or Conventional (C). People search for, do well in, and feel satisfied with environments that are congruent with their personality types. "R" describes "doers" who like to work with tools or machines and generally avoid intensive interaction with people. "I" describes "thinkers" who enjoy analyzing and investigating but avoid leading and selling, or persuading people. "A" individuals are "creators" who like creative activities such as art, drama, or creative writing, and generally avoid highly ordered or repetitive activities. "S" are "helpers" who enjoy helping people such as teaching, counseling, or nursing, and generally avoid situations involving operation of tools and machines. "E" people are "persuaders" and like to lead, manage, and persuade people, and avoid activities that require careful observation and scientific,

analytical thinking. Lastly, "C" people are "organizers" and like to work with numbers, records, and keep things ordered and structured. These six types are described in a hexagonal configuration and this theory is often known as Holland's hexagon model. According to this framework, individuals typically are not "pure" of one type; rather they are a combination of several types with one or two more dominant types. Therefore, many of the career interest inventories based on this model will use a three letter-code to represent the first three most significant types, also known as Holland's theme code.

Self-Directed Search (SDS)

The SDS was originally developed by John Holland in 1970 based on his theory of career development and is currently in its fourth edition revised in 1994. SDS is a self-administered, self-scored, and self-interpreted inventory that is available in paper-pencil, computerized, and most recently, online formats. Form R (Regular) is the most commonly used SDS, appropriate for high school students, college students, and adults. It has 228 items asking examinees whether they like certain activities, have confidence in certain competencies, are interested in and appealed to certain occupations, and to estimate their abilities on a 7-point Likert-type scale. From these responses, scores are obtained on each of the six RIASEC types and the examinee's Holland theme code is generated based on the rank of these scores. These scores can be used in combination with auxiliary materials that include *The Occupations Finder*, *The Educational Opportunities Finder*, and *The Leisure Activities Finder*. These materials contain lists of occupations, educations, and leisure activities classified according to the Holland system, with each occupation, education, and leisure activity having its own Holland theme code. Apart from the purpose of self-understanding, SDS in combination with these materials can help an individual generate career choices that are congruent with their personality types and determine where the best fit may occur between the person and the environment.

Reliability studies with the fourth edition indicate strong internal consistency and test-retest reliabilities. Readers are referred to the SDS Professional User's Guide by Holland and colleagues (1997) and Further Reading for detailed evidence of reliability and validity.

Strong Interest Inventory (SII)

The Strong Interest Inventory, also known as the *Strong*, is one of the most widely used assessments of interests. It was originally developed and published as *The Strong Vocational Interest Blank* (*SVIB*) in 1927 by E. K. Strong. SII has been substantially revised over the decades. David Campbell made the first major revision in 1974 by incorporating Holland's hexagonal model and SVIB was renamed as *Strong-Campbell Interest Inventory* (*SCII*). Holland's mode continues to be the foundation of all the following revisions. SCII was revised again in 1981 and 1985 to include gender-balanced scales with equitable career options for both men and women. The 1994 revision greatly increased the sample sizes of the male and female norms. SII was most recently revised as a whole in 2004 with a purpose of shortening the inventory, updating it with current occupations, and reflecting the diversity of the U.S. workforce.

The current SII has 291 items and provides four main types of information concerning one's interests: (1) scores on six General Occupational Themes (GOTs) corresponding to Holland's RIASEC types, (2) scores on 30 Basic Interest Scales (BISs), which describe the general interests in more specific areas, (3) scores on 122 Occupational Scales (OSs), which represent the degree of similarity between one's interests and the characteristic interests of those working in such occupations, and (4) scores on five Personal Style Scales (PSSs) that summarize one's orientation with respect to work style (i.e. alone vs. with people), learning environment (i.e. practical vs. academic), leadership style (i.e. comfortable vs. uncomfortable in assuming leadership), risk-taking (like vs. dislike risk-taking), and team orientation (working on teams vs. working independently). SII also provides the Administrative Indexes that help identify inconsistent or unusual responses and invalidity of the profile. The SII was most recently updated in 2012, focusing on OSs only to keep them as current as possible. The newly updated OSs include 130 scales that are separate for males and females and have been integrated in the *Strong* family of reports.

Reliability and validity of SII have been supported by many studies. Both the internal consistency reliability and the test-retest reliability have improved in the most recent revision. Readers are referred to the SII Manual by David Donnay and colleagues, published in 2004, for details of its reliability and validity.

Assessment of Career and Vocational Abilities

General Aptitude Test Battery (GATB)

GATB, published by U.S. Department of Labor in 1982, has been one of the most widely used test batteries assessing abilities. In general, GATB intends to measure abilities required for many occupations. It measures a broader range of abilities than many academic aptitude tests. Specifically, GATB can provide information on an individual's ability profile across the following nine general areas: General Learning Ability (G), Verbal Ability (V), Numerical Ability (N), Spatial Ability (S), Form Perception (P), Clerical Ability (Q), Eye/Hand Coordination (K), Finger Dexterity (F), and Manual Dexterity (M). Apart from assessing individuals' abilities in career counseling and development, GATB has been used by the U.S. Department of Labor to generate occupational ability patterns that characterize the occupations in terms of their requirements of abilities for a variety of jobs. While GATB continues to be used as an assessment of career abilities, the U.S. Department of Labor has updated it to O*NET (*Occupational Information Network Online*) Ability Profiler (AP) which measures a similar set of abilities. The O*NET Ability Profiler is used as a career exploration tool that helps clients identify their strengths and find occupations that fit their strengths.

Skill Confidence Inventory (SCI)

SCI is 60-item inventory assessing one's perceived ability to successfully complete a variety of tasks and activities that correspond to the six Holland types. The SCI has been integrated in use with SII and the confidence scores are aligned with the *Strong*'s GOTs. Apart from

the levels of skills confidence corresponding to the GOTs, SCI provides the Skills Confidence-Interest Comparison, which compares levels of confidence with levels of interests revealed by SII. The integrated use of SCI and SII helps examine individuals' interests and perceived abilities simultaneously to understand their interest patterns and thus provide information that neither inventory provides alone.

Further Considerations

Although assessment of career interests and abilities provides important information for career counseling and career development, some cautions and considerations should be kept in mind in use of these assessments. Interests tend to become progressively stable with age, but changes in interests are always possible. Just as one can obtain new abilities and skills through training, one's perceived ability can also increase as a result of career counseling. It is important to keep a dynamic perspective to view the impact of one's interests, abilities, and perceived abilities, as well as their interactions with one's career choices and development. Moreover, like many other self-report inventories, interest inventories are subject to response bias; therefore, scores from assessments of career interests and abilities should be interpreted in the context of one's profile validity, as well as the examinee's testing behavior and emotional states. Interest and ability inventories may not be appropriate for individuals with emotional distress, such as depression or mania, as they may strongly affect their scores.

Cognitive Aging, Assessment of

F. R. Ferraro

University of North Dakota

What is Cognition?

As discussed in "Assessment of Cognitive Processes and Abilities, General Features and Methodological Issues" (Ferraro, in press), cognition is how individuals think, problem solve, make decisions, speak, walk, and perform a whole host of information processing activities. Since many of these information processing activities are internal mental representations of actual events, one must be careful regarding how one measures these actions and processes. Reaction time (RT) is one of the most common methodologies employed to measure and study internal mental representations. Likewise, RT is often one of the more controversial methodologies.

What is Aging?

By definition, adulthood and aging is the period from approximately 20 years of age until death. Developmental psychologists, by comparison, study aging (i.e. there are chapters dealing with late-life-development in many developmental textbooks) but they also study pre-natal and pre-adulthood development phases of life. Aging can actually be broken down into various subcomponents which include early adulthood, middle adulthood, and late adulthood. The actual age ranges of these subcomponents vary, but it is generally agreed upon that early adulthood ranges from 20–40, middle adulthood ranges from 40–60 and late adulthood ranges from 60–death. As mentioned, these ranges are variable, most likely due to longevity and life-expectancy issues. For instance, life expectancy for both men and women increases each year. Furthermore, there are more centenarians (those who live to be 100 years of age or older) in the United States and one of the fastest growing age groups currently are those individuals aged 65 and above as well as those 85 and above.

Thus, middle age 30 years ago is vastly different from current middle age. For the purpose of this entry, I will be concentrating on issues as they relate to late adulthood.

Personality Aspects of Cognitive Aging

Despite many positive and negative changes with age, personality for the most part seems age-invariant. That is, many personality traits (i.e. Big Five; Costa & McCrae, 1992) remain relatively constant across early, middle and late adulthood. While there are no (or very few) age differences, there are substantial cohort differences. Thus, many of our personality changes with age are based on what we have experienced as we age as compared to just age alone.

   Similarly, the assessment of cognitive function in age can also be influenced by the specific type of experimental design used by the researcher(s). For instance, most studies of cognitive aging rely on cross-sectional types of experimental designs in which a group of young adults is compared on some task or collections of tasks to a group of older adults (now often broken up onto middle age and old age groups). Such designs are relatively easy in that subjects need only participate one time. Conclusions can be drawn but the elusive cohort confounding that often plagues such designs are not immediately apparent. In other words, an experimenter may show age differences on some task (younger faster than older, older faster than younger, etc.) but little more. Cross-sectional types of designs do not allow for the investigation of cohort differences. Thus, the relative ease of cross-sectional designs is hampered by not being allowed to fully investigate possible (and most likely probable) cohort influences across the two (or three) groups of subjects. An alternative to cross-sectional designs are the so-called longitudinal designs, in which subjects are tracked and assessed more than once and typically over a period of several years. A plus of the longitudinal design is that individual change can be assessed and examined (which is not the case in cross-sectional designs). However, assessing and examining such individual change is costly, subjects either die or decline continued participation, and it is somewhat tricky to make lasting conclusions because time of measurement problems are typical (Feng, Silverstein, Giarruusso, McArdle, & Bengston, 2006). To remedy these (and other) potential problems with longitudinal designs, Shaie (1990) developed cohort-sequential designs, which combine aspects of cross-sectional and longitudinal designs and allow for the teasing apart of true age effects from effects due to cohort issues. Because of their costly nature, large samples sizes and lengthy duration (30–40 years or more), few of these sorts of designs are attempted. However, within the cognitive aging literature, two such endeavors stand out (Baltimore Longitudinal Study of Aging, Seattle Longitudinal Study on Intelligence) as having contributed much to the assessment of cognitive function and aging.

Individual Difference Aspects of Cognitive Aging

Another somewhat surprising aspect of aging is that various individual differences are apparent through the aging process and have resulted in the reduction in the proliferation of some myths regarding the aging process. For instance, it is now common to break

down the late adulthood stage into the young old (65–85) and the old-old (85 and above). Given the increases in the number of centenarians and even so-called super centenarians (110 and older), there are now many individual differences that extend into our 80s, 90s, and beyond. One variable that has gained much attention recently in the cognitive aging literature involves reaction time. Specifically, in what are called Brinley (1965) plots, reaction times to tasks undertaken by younger and older adults show evidence of where age differences exist and where they do not. Brinley plots examine cognitive slowing, which is a fundamental outcome of even normal healthy aging. That is, our information processing system slows with age such that we slow a little bit each decade we are alive. Slowing begins its decline at around age 20 and continues thereafter. Older adults often compensate for these slowing patterns but Brinley plots allow for an examination of what processes slow and to what extent they slow. The slope of the best-fit line through a series of RT points is an indication of slowing. If, for instance, the slope of a best-fit line is 1.0 that would indicate there is no slowing and younger and older adults are responding similarly. Conversely, a slope of 1.5 would indicate that older adults on some specific task are 1.5 times slower than their younger adult counterparts who participated in the same experimental conditions. While not everyone agrees with the Brinley plot analysis, it has been very helpful in delineating what slows with age and to what extent it slows.

Although this entry has discussed reaction time methods, others are also available to examine a multitude of cognitive functions in aging including problem solving, decision-making, learning and memory as well as text comprehension. While many of these involve reaction time, that is not the only method of assessment. Real-life scenarios involving tasks relevant for older adults (i.e. financial planning, medication adherence, social interaction) also tap into a multitude of cognitive processes and processing, especially issues related to planning, decision-making, and problem solving. Inherent in many of these endeavors is a properly functioning frontal lobe. The frontal lobes decline normally as we age, yet this part of the brain is actively involved in many underlying cognitive processes (Cabeza, 2004) and its decline often leads to problematic cognitive functioning in older adults. These can include problem-solving difficulties, incorrect or impulsive decisions, or aspects of planning that are not adequate for the task at hand. Recent advances in brain imaging (especially magnetic resonance imaging (MRI) and positron emission tomography (PET)) have shown how the aging brain operates in times of frontal lobe deficit and other related cognitive actions. These techniques show promise and have been used extensively within the aging population (Winecoff, LaBur, Madden, Cabeza, & Huettel, 2011).

Future Directions

Given the longevity and life-expectancy issues discussed previously, the future of aging's effect as it relates to personality and individual differences seems very promising. In fact, despite the controversy surrounding Brinley plots (see Fisk & Fisher, 1994), recent reports indicate the usefulness of Brinley plots with regard to functional brain imaging and aging (Peiffer, Maldjian, & Laurienti, 2008).

Creativity, Assessment of

Susan Snyder and Lauren M. Littlefield

Washington College

Concepts and Constructs

Progress often depends upon creative thinking – the inventive, subjective, and free form thinking that generates alternate viewpoints, curiosity, and imagination. Currently, there are countless definitions of the construct and no commonly agreed upon version, although a generally accepted characteristic is a distinct and productive concept or thought. The measurement of creativity has also taken on various forms, although one aspect of measurement that has been generally adopted is divergent thinking, the ability to produce as many appropriate responses as possible in a limited amount of time. Influences of personality and cognitive traits have been found to factor into the measurement of divergent thinking. Three factors of intellectual ability that play a role in divergent thinking have been proposed: fluency of thinking – verbal, ideational, and associational; flexibility of thinking – spontaneous thinking; and originality – uniqueness of thought. Fluency of thinking is primarily the capacity to have a ready flow of ideas; flexibility is marked by the ability to quickly change direction; and originality is the ability to be versatile in thought. These aspects of creative thought production can be assessed through verbal and non-verbal methods. Divergent thinking is often correlated with commonly studied creative personality traits such as openness in the Five Factor Model and the psychoticism scale of the Eysenck Personality Inventory.

Personality and Attitude Assessments

Although the link between creativity and personality has been extensively studied, the personality variables related to divergent thinking do not render consistent findings across studies. There are several inter-correlations worthy of consideration. Eysenck and Eysenck's (1976) dimensions of extraversion and introversion (E), neuroticism and stability (N), and psychoticism and superego (P) yield some clear and reliable patterns to suggest that they are stable traits in the personality structure. Extensive research has also been conducted

showing correlations between openness, extraversion, and divergent thinking. For example, through early work using Eysenck's Personality Questionnaire with a large sample students, Di Scipio (1971) revealed that people who were more outgoing showed significantly higher fluency scores than those who were more reserved. In a more recent study on divergent thinking by Furnham and Bachtiar (2008), 176 participants were tested in a group setting to find that there were significant relationships between openness, extraversion, and divergent thinking. Furthermore, McCrae (1987) consistently found peer ratings and self-reports of divergent thinking related to openness.

Some evidence suggests that mental illness is related to creative behaviors. Increased energy, flights of ideas, and possessing hypomanic personality traits (such as higher extraversion and higher openness) have been associated with the proliferation of creative works. Additionally, Eysenck suggests that highly creative people often show personality characteristics closely related to schizophrenia or other psychotic disorders. Studies have used artistic achievement as a means of measuring originality and creativity. Some work has found a significant correlation between psychoticism and creativity, enhancing the hypothesis that certain personality traits are more prevalent in creative people. However, it has also been shown that psychoticism is not a necessary characteristic to exhibit creative tendencies and that the throes of psychosis can cause productivity to significantly decline. Although this is a fascinating topic that has been studied from many angles, more work is needed to substantiate relationships between creativity and personality traits associated with various psychiatric diagnoses.

Sensation seeking has also been linked to the creative personality. According to Zuckerman (1994), sensation seeking is a personality trait encompassing the willingness to take significant risks in the pursuit of novel and intense experiences. Sensation seeking can be broken down into four subcomponents based on factor analyses conducted by Zuckerman and his associates in the 1960s. Thrill and Adventure Seeking involves a drive toward unusual sensations through risky activities. Experience Seeking pertains to practical influences that contribute to novel experiences (like driving and sports). Disinhibition is characterized by a drive to be free of social constraints. Boredom Susceptibility is the propensity to avoid monotonous situations. These subcomponents that define the sensation-seeking trait mimic the motivation for developing unique and creative ideas. Therefore, just as divergent thinking is the ability to render unusual solutions to problems, sensation seeking is the contemplation of unconventional ways to discover novel experiences. These two traits, divergent thinking and sensation seeking, seem to complement each other to build the platform for producing new and interesting ideas.

Measuring Divergent Thinking

A number of psychological tests have been developed for the purpose of quantifying creativity in the form of divergent thought. Several popular tests are summarized. A common theme is that validity evidence for the measures is weak. While there is some evidence of construct validity, more research is needed in order to produce solid criterion-related validity such that the scores produced would also be related to important outcomes or predictions in the real world.

Torrance Tests of Creative Thinking

This test was originally designed to identify students with creative potential by measuring fluency, flexibility, and originality. The test is administered with pencil and paper and contains two sections, a verbal one consisting of seven subtests and a figural one consisting of three subtests. Although the test is easy to administer and score, the reliability and validity of the test should be approached with caution due to varying testing environments, interpretation of scores, and lack of standardized administration procedures. However, the inter-correlations between the subtests have been shown to be adequate enough to indicate that the subtests are tapping into similar capabilities.

Calibrated Ideational Fluency Assessment

This assessment is a paper and pencil measure with two subtests, verbal fluency and non-verbal fluency. The verbal fluency section has two one-minute tests for spontaneous production of letter word fluency (producing as many words as possible that begin with a certain letter) and two one-minute tests for category word fluency (producing as many words as possible fitting the categories of supermarket items and animals). The non-verbal fluency subtest requires participants to produce as many drawings as possible with the same four parts in four minutes. To earn credit, the designs are compared to standardized scoring samples. Additionally, the designs cannot be recognizable or nameable, and each drawing has to be different. Interrater reliabilities were assessed using intraclass correlation coefficients and ranged from .87 for total word fluency scores to .97 for acceptable design fluency scores. The validity of this test has been shown to be effective for assessing divergent thinking and shows high test-retest stability.

Guilford Alternate Uses Measure

Recent studies have used this method to assess divergent thinking fluency. Participants are given two minutes for each item, i.e. a tissue and a lint roller, to identify as many uses as possible. This test is scored by counting the number of feasible uses produced. Additional scores are recorded for originality by counting the number of unique or remote responses, and flexibility by counting the number of diverse responses in varying categories of ideas. These scores are subjectively determined by one rater to reduce the error of variance. This test is designed to measure the number of novel ideas of the participant in comparison to the total number of ideas, therefore measuring divergent fluency as related to creative potential.

Creative Intelligence

A large amount of research has been done correlating intelligence with creativity. A traditional way to subdivide intelligence into two dimensions involves crystallized intelligence (*gc*), which is the ability to organize and use conceptual information, as opposed to fluid

intelligence (*gf*), or reasoning ability. Batey, Chamorro-Premuzic, and Furnham (2009) proposed that cognitive efficiency plays an important role in rapidly producing fitting responses to divergent thinking tests. However, the results of their research showed that fluid intelligence was not markedly related to divergent thinking; therefore, intelligence seems loosely related to creativity.

Sternberg (2005) presents the Theory of Successful Intelligence, which provides a broader view of intelligence by breaking it down into components of analytical intelligence – evaluation and judgments of abstract theories; creative intelligence – evaluation of novelty in problem solving; and practical intelligence – applying adaptive behaviors to suit the environment. This theory, sometimes referred to as *triarchic* because of its three subtheories, reveals that creativity and its relationship to intelligence are not simply based on conventional information processing.

Sternberg and Lubart constructed the *Investment Theory of Creativity* to explicate why some people have more creative ability than others. There are six areas of creativity considered in this theory – intelligence, knowledge, intellectual styles, personality, motivation, and environment, with the last area being the only one that is context-centered and the rest being focused around the person. Each area highlights an aspect of creativity that contributes to the creative product; however, it is also discerned that it is not necessary to have full involvement of each resource in order to produce creative thoughts or actions. The Multifaceted Assessment of Creativity was designed to characterize the six resources of the Investment Theory of Creativity. The measure was found to have high internal consistency and validity for assessing the six dimensions of the Investment Theory of Creativity, lending insight that it is possible to develop creativity among the six areas.

The Future of Assessing Creativity

Creativity has become a topic of psychological research that continues to develop, with over 10,000 papers written in the past decade. In spite of that, the definition and nature of creativity still remain under debate. Kaufman and Beghetto (2009) have attempted to expand the model of *Big-C* creativity, which identifies those who excel at very high levels of creativity, and *little-c* creativity, which focuses on everyday creative thinking. They propose to add additional facets of creative potential, *mini-c* and *Pro-c,* to this theory to close the gap of what is recognized as creative potential. The category of mini-c is designed to include how creativity is employed during the learning process. On the other hand, Pro-C represents those who have reached a status of expert in their creative approach. By expanding the model, a new level of complexity emerges and expands the boundaries of areas to explore and research.

While there many theories of creativity and methods available for its measurement, creativity remains a fairly abstract concept. Future research needs to clearly state the operational definitions of creativity used and establish ecologically valid indicators of creative talent. Identifying key personality traits, such as sensation seeking, extraversion, and openness that appear to be highly correlated with creative thinking might assist in the identification of ingenious children and the selection of imaginative employees. A more developed understanding of the interaction between cognitive behaviors and personality traits would provide insight into how people interact in a problem-solving environment.

Educational Ability Testing (GRE/MAT/MCAT/LSAT)

Natalie Abraham[1] and Amanda ElBassiouny[2]

[1] *Spring Hill College*
[2] *California Lutheran University*

Educational ability testing refers to the capacity of psychological tests to assess samples of students' skills, knowledge, or any cognitive functions or processes. These tests are called ability tests and within the education field they are often referred to as standardized tests. Standardization refers to when all ability tests are administered, scored, and interpreted in an objective and highly regulated manner. These standardized tests are taken under same conditions for every test taker. Within this technique of standardization, scores for students are calculated by comparing them to normative data, which is determined from a group that was used during the developing process of making the test. Raw test scores are transformed into standard scores so that a student will know how they are performing in comparison to others who have taken the exam. The standard scores are strictly based on the distributions of the normal curve and percentile rank. A student's score is now comparable to his or her own overall ability, another student, to a group, or the population (Ross-Kidder, n.d.).

These ability tests are used as tools to evaluate the academic achievement of students, a student's mastery in a specific domain, or the use of particular skill in question. These scores are used to make decisions about awarding scholarships, qualifying for degrees, or determining readiness to proceed to a more advanced level of training (Goslin, 1963). The main purpose of these tests is to help make these decisions as objectively as possible.

Throughout history, psychological tests were used as tools to make decisions about people. Ability testing in the education setting was first introduced during the Middle Ages with the rise of universities in Europe. The tests were used to measure how much knowledge a student retained from what was being taught in school. During this period, degrees earned at a university were used a certification to teach. Oral tests were administered to evaluate the candidates for the degree. However, with the evolution of education, traditional oral tests were widely replaced with paper and pencil tests.

Educational ability testing became the conventional tool for evaluating the conferment of degrees in both Europe and the United States by the nineteenth century. One of the first

waves of ability tests created and used to evaluate elementary students is the Stanford-Binet Intelligence Scale developed by Alfred Binet. His test led to the technique of administering an exam by one examiner to large groups of people at one time, such as military groups. After World War I, group testing had been proven efficient and accurate and intelligence tests were developed to give to high scoring graduates. By the 1920s, the number of ability tests that were being published increased greatly (Urbina, 2014).

Henry Chauncey, a lawyer and educator, developed the Educational Testing Service (ETS), which helped encourage the movement toward the widespread use of standardized testing and assessment in the 1940s. The objective for ETS was to ensure that every student had an equal opportunity to be considered during admissions decisions. Prior to ETS, schools would use a student's class and status when making admissions decisions, rather than a student's knowledge and abilities (Goslin, 1963).

Consequently, educational testing ability became very influential to admissions processes as the number of students in all levels of education began to increase. It was necessary to have ability tests that were standardized. This led to two major branches of educational testing, many of which includes tests that are operated by ETS. The first branch is the standardized achievement tests. These tests had become the primary resource in elementary and secondary education to assess student's skills in arithmetic, reading, spelling, and other subjects. Currently, standardized achievement tests are used in educational environments and have expanded to licensing and certification purposes in the professional realm. The second branch of educational testing is the scholastic aptitude tests. These tests were used by colleges and universities as part of students' applications that determine admission decisions. The most recognized test is the Scholastic Aptitude Test or in short the SAT. Other tests in this branch include the Graduate Record Exam (GRE), Medical College Admission Test (MCAT), Graduate Management Admission Test (GMAT) and the Law School Admission Test (LSAT). While each of these has specific fields that they address, every test has a verbal, quantitative, and reasoning section (Urbina, 2014).

At the present time, ETS is the world's largest private educational testing and measurement organization. They develop, administer, and score tests. The have a process for designing, developing, and administering assessments through an extensive 10-step process (Educational Testing Service, 2016). Additionally, equating procedures are utilized to allow colleges and universities to compare test scores over the years to monitor trends and update norming data.

Currently, colleges and universities typically use educational testing internally. A main purpose for them includes assessing the abilities of incoming students both individually and collectively. One of ETS's most popular tests that many graduate institutions have adopted is the GRE. The most recent form is now the GRE, the revised General Test. The GRE is one of the heaviest weighted components of a student's application for graduate or business school. The format of the test contains a verbal reasoning, quantitative reasoning, and an analytical writing proponent (Educational Testing Service, 2016). The predictive validity of the GRE has been explored since it is such a heavily used tool in the admissions process and it has been found that a combination of both GRE and a student's grade point average is reliable for predicting his or her success in a graduate program. Colleges and universities will, therefore, use these two components together to filter applications (Ingram, 1983).

Emotional Intelligence, Assessment of

Reneé R. Boburka

East Stroudsburg University

In the early 1990s, Salovey and Mayer initially described the concept of emotional intelligence (EI), which is considered the ability to perceive, access, generate, understand, and regulate emotions so as to enhance emotional, social, and intellectual growth. They proposed that individuals differ in their abilities to effectively utilize emotions, in that some individuals are better able to use emotions to enhance their relationships with others. Theorists often align the concept of EI with theories of general intelligence, such as the classic intelligence models of Gardner, Sternberg, and Wechsler. For instance, Wechsler included in his 1950 conceptualization of intelligence the concept of non-intellectual factors that either facilitate or inhibit intelligence. He did not include EI as a formal construct in his original theory, but he did contend that factors not directly related to intellectual ones should be included in the concept of general intelligence.

In the time since the concept was introduced, EI has exploded, even entering the mainstream. In 1995, Goleman was largely responsible for bringing EI to a broader public audience, making claims that EI could account for the differences between those who excel at their jobs versus those who do not. His conceptualization linked EI with other aspects of personality as well, such as maturity and character. Goleman even described EI as being a better predictor of success than traditional forms of IQ. However, most researchers today contend that both EQ and IQ are important in predicting various aspects of success.

Ability Versus Trait Measures

In its original conceptualization, EI was viewed as a set of interrelated abilities. The ability approach treats EI more like a traditional form of intelligence, based on the notion that it is likely to correlate with cognitive ability tests. The flagship of EI assessment for those who adhere to the ability-based view is the Mayer-Salovey-Caruso scale, which is now in its second version (MSCEIT 2.0). According to Mayer, Caruso, and Salovey (2000), the MSCEIT 2.0 measures four hierarchically ordered EI branches: (1) accurately perceiving and

expressing emotions, (2) using emotions to facilitate thoughts in problem solving, (3) understanding emotion, and (4) managing and regulating emotions. Ability-based assessments are considered objective in nature because the developers have attempted to identify the correct answers to the test items. The objective items on the MSCEIT 2.0 are scored via a consensus technique, in which each test taker's response is scored according to: (a) the consensus response of the judgments of hundreds of others who have answered the same item, and (b) expert consensus consisting of pooled judgments from a group of experts in the field. These two scoring approaches are highly correlated with each other.

Additional ability-based measures are the Situational Test of Emotional Understanding (STEU) and the Situational Test of Emotion Management (STEM) developed by MacCann and Roberts (2008) for the purpose of providing other performance-based ability instruments for use in EI research. They also implemented a scoring method based on theory, rather than consensus. The Boyatzis-Goleman model was inspired by early works of Mayer, Salovey, and Caruso and consists of 20 specific competencies organized into four clusters: self-awareness, self-management, social awareness, and social skills (Boyatzis, Goleman, & Rhee, 2000). The primary measures associated with this model are the Emotional Competence Inventory (ECI) and the Emotional and Social Competence Inventory (ESCI). Both of these scales have multi-rater report measures, which can include self-ratings, but can also have others rate the test taker as well (peers, customers, supervisor, etc.). Another self-report measure used to measure ability-based EI is the Wong and Law Emotional Intelligence Scale (WLEIS), also based on the original Salovey and Mayer model. The WLEIS measures self emotional appraisal, others' emotional appraisal, and use and regulation of emotion (Wong & Law, 2002).

Other theorists, such as Bar-On, have defined EI as a mix of traits (e.g. happiness, self-esteem, optimism, etc.) rather than interrelated abilities. This EI conceptualization, often called the trait, or mixed, approach, includes the assessment of non-cognitive abilities, competencies, and skills, which enable individuals to successfully adjust to the emotional demands of various situations. Bar-On was interested in identifying various traits and skills that people use in their real-life social and emotional encounters. He suggested that EI traits and skills include: (a) the ability to be aware of, and to understand, the self and others, (b) being able to express oneself, (c) being able to control one's impulses, (d) the ability to adapt to change, and (e) the ability to solve social problems. His scale, the Emotional Quotient Inventory (EQ-i), is a trait-based, self-report measure (Bar-On, 1997). It provides an overall EI score and sub-scores in the following areas: intrapersonal skills, interpersonal skills, adaptability, stress management, and general mood. Trait models typically utilize a self-report technique (e.g. I understand my emotions well), relative to the more objective ability-based scoring technique. Other self-report instruments include the Trait Emotional Intelligence Questionnaire (TEIQue) by Mikolajczak, Luminet, Leroy, and Roy (2007) and the popular Self-Report Emotional Intelligence Test (SREIT), which is based on the Mayer, Salovey, and Caruso model (Schutte et al., 1998).

These seemingly discrepant conceptualizations of EI (i.e. ability versus trait) have created some confusion, in that measures of EI seem to assess two different constructs and there does not appear to be a strong association between the ability-based measures and the self-report measures. In addition, some theorists have even criticized the concept of trait-based EI saying that it covers too many different traits.

Emotional Intelligence as a Traditional Intelligence

Of great interest in the study of EI is its relation to traditional forms of intelligence. Whether EI is an actual intelligence has long been debated by numerous theorists. Ability-based proponents argue that EI is a type of intelligence, and therefore the two constructs should be moderately correlated. Mayer, Salovey, Caruso, and Sitarenios (2001) contend that EI does indeed meet the standards to be classified as a traditional form of intelligence. Trait-based measures, however, tend to have weak correlations with traditional measures of intelligence (Saklofske, Austin, & Minski, 2003) and trait-based proponents do not claim that EI is an actual type of intelligence. A number of theorists contend that trait and ability-based EI should be considered as two distinct entities and that the relation between EI and cognitive ability likely depends on the method being used to measure EI.

Emotional Intelligence and Personality

In attempting to understand the mechanisms operating in EI, many researchers have investigated the relationship between EI and different aspects of personality. Various theorists have even suggested that if EI is highly correlated with personality traits, then the EI model may not contribute new information outside of what is already known from the personality research. For instance, Saklofske et al. (2003) contend that the typically large correlations between trait measures of EI and traits from the Big Five Model of Personality show that trait-based EI is so similar to personality theory that it potentially does not add any new knowledge. However, the correlation between ability-based measures and personality is less concerning, given that most studies have revealed small or no correlations. A meta-analysis by Van Rooy, Viswesvaran and Pluta (2005) supports the claim that ability-based EI is distinct from personality. They found that while some self-report measures of EI did correlate with personality measures, ability measures tended to not correlate with personality. Therefore, it appears that whether the measures are correlated with personality depends on the type of measure used.

What Can Emotional Intelligence Predict?

One of the reasons why the topic of EI has become so popular is because of the extensive list of outcomes with which it has been associated. Following is a list of various outcomes that have been potentially predicted by higher ability and/or trait EI scores:

- Success in the workplace, including merit raises, performance evaluations, and workplace morale
- Increased social competence, more successful interpersonal relationships
- Greater well-being, general health, higher ratings of happiness and self-esteem
- Decreased tobacco, drug, and alcohol use
- Lower levels of depression, anxiety, loneliness, and less interpersonal conflict
- Greater achievement and life satisfaction
- Better grades in school and reduced behavior problems.

Gender and Cross-cultural Comparisons

For the ability-based MSCEIT 2.0 scale, women often score higher than men. Several studies utilizing self-report EI measures have also found that women tend to score higher than men. However, other researchers, using similar measures, did not find significant gender differences. To muddy these conclusions even further, some studies utilizing trait measures have found that women tended to score higher in the skills related to feeling and expressing emotions, whereas men tended to score higher in skills related to the handling of emotions and optimism (Bindu & Thomas, 2006). Siegling, Saklofske, Vesely, and Nordstokke (2012) suggest that trait EI is more strongly associated with stereotypically masculine traits, and that ability EI is more strongly associated with feminine traits. They further indicate that this could be especially problematic given that trait measures are self-report in nature, and these types of measures may be especially susceptible to perceptions based on common stereotypes. Correspondingly, a meta-analysis by Joseph and Newman (2010) suggested that gender differences in EI depend primarily on which measure and theoretical approach is used.

When considering cross-cultural comparisons of EI, some research has found that scores on the MSCEIT 2.0 tend to generalize across cultures with similarities found between individuals from collectivist and individualistic samples. However, other research, such as classic studies by Matsumoto, has found that individuals from a more individualistic culture may be better at understanding, expressing, and regulating emotions, relative to those from a more collectivistic culture. Therefore, the conclusions for cultural comparisons in EI are still unclear and require further clarification.

Genius, Assessment of

Femina P. Varghese, Jon Nolan, and Catherine Allen

University of Central Arkansas

History

Among the foremost researchers of genius in the modern era is Dr. Dean Keith Simonton. According to Simonton, the term "genius" has been around since ancient mythologies in diverse cultures; ancient Greeks saw genius as a divine nature in every person and this was later adapted by the Romans. Simonton further relates that Western thought dropped the divine characteristic of genius, but retained the innate qualities. Immanuel Kant (1934/1781) and later Francis Galton emphasized in their definition of genius that natural abilities are key, and Galton was among the first to measure the construct of genius. Simonton indicates that Galton also notes that along with mental abilities persistence and passion are important, whereas for Kant originality and creativity mattered. Simonton sees that each of these components are part of genius.

Intelligence Tests

A history of intelligence testing as presented by Shultz and Shultz reveals that the first test to measure cognitive ability as it is understood today was developed by Alfred Binet and Theodore Simon who believed that mental ability measures should include problem solving, memory, attention, and imagination. This basic formula was then adapted by Lewis Terman in 1916 as he developed the Stanford-Binet intelligence test. The Stanford-Binet produced an intelligence quotient (IQ) based on an individual's mental age (as computed by the test) divided by that individual's chronological age. The Stanford-Binet and its subsequent adaptations assess intelligence over a variety of cognitive abilities including fluid reasoning, verbal and quantitative reasoning, spatial processing, and working memory for children ages 4–10. In relation to genius, it was the developer of the Stanford-Binet, Lewis Terman, who first linked IQ scores with the term. Currently

scholars and practitioners indicate that the fifth edition of the Stanford-Binet Intelligence Scales is considered useful in detecting "genius" level intelligence as it is considered to have a high ceiling.

The Wechsler Adult Intelligence Scale (WAIS) is another psychological assessment instrument that seeks to gauge an individual's intelligence. There are important differences in the WAIS from the Stanford-Binet. In his review of the WAIS, Silva (2008) explains that the WAIS provides subjects multiple IQ scores including full-scale IQ (FIQ), performance IQ (PIQ), and verbal IQ (VIQ). Furthermore, the WAIS no longer relied on the Stanford-Binet method of acquiring IQ scores by dividing mental age by chronological age; instead, the scores on these measures were based on an individual's performance based in comparison to established norms ($M = 100$, $SD = 15$) acquired by a large sample of scores from individuals in a particular age range. The WAIS does not specify a cutoff for genius, but gifted is 130 and above. Tests such as Stanford-Binet and WAIS have been criticized by Howard Gardner and Robert Sternberg, who argue they are too narrow and argue for multiple intelligences.

In support of Gardner and Sternberg are findings from the famous genius project led by Lewis Terman. Terman followed the lives of children who had scored over 140 on the Stanford-Binet, putting them at the very highest percentage (1%) of people in terms of intelligence. However, a follow-up analysis of children acquiring "genius" status by psychological researcher Feldman (1984) indicated that though individuals with high IQs were able to more easily thrive in academic endeavors and were generally well-adjusted throughout adulthood, the likelihood of achieving excellence or distinction in a particular field was not as predicted. While the Stanford-Binet focused on assessing the cognitive abilities of children, other intelligence tests include the Weschler Adult Intelligence Test and the Raven's Progressive Matrices; however, no single intelligence test has ever reliably been established as an accurate assessment of genius.

Historiometric Measurement of Genius

Dean Simonton believes an even more reliable measurement of genius is looking at historiometric ways of assessment. Simonton defines genius as mastery over a certain domain that distinguishes someone from all others. Therefore, Simonton believes the best way to measure this is through extraordinary products that are creative, novel, and valuable to society. Simonton has noted that above average intelligence is associated with such extraordinary products and support for this measure of genius are seen in the works of Leonardo Da Vinci, Benjamin Franklin, Galileo and others who produced extraordinary works in multiple areas.

Important to the development of such original and extraordinary products is creativity. Tests of divergent ability have been one way to test creativity. Kubin and colleagues noted that the lack of high achievement in Terman's "Termites" was attributed to a lack of creativity. Simonton states that personality traits can also measure creativity and could be assessed by personality inventories (e.g. MMPI).

Brain Functioning

New approaches to examining intelligence include studying the brain and its role in intelligence. An interesting and related finding by Witelson, Kigar, and Harvey (1999) is the high amounts of idiosyncratic axonal connectivity found in the post-mortem brain of Einstein. Studies have indicated that gray and white matter in the brain may influence intelligence. Intelligence tests have shown correlations with both gray and white matter, with the latter related to deftness in sharing of information across different brain regions as revealed in research by Colom and colleagues (2010). Many researchers in the field have related that intelligence has been linked with the brain's ability to communicate effectively and efficiently via dense neural networks. Deary and colleagues (2010) bring attention to the fact that this efficient processing conception of intelligence provides a basis for the concept of general intelligence (*g*) in that those who are intelligent in one area tend to be intelligent in another perhaps because of efficiency in processing.

Considerations of Social Class, Gender, Race

Since the conception of genius, there has been consideration about the role of genes (nature) and environment on intelligence and, since the measurement of genius, the role of bias in measures in regard to social class, race, and gender. An article by Nisbett (2012) and colleagues in the *American Psychologist* (AP) reported that intelligence is influenced by genes and environment, and suggested that impoverished environments appear to limit the development of a person's intelligence. They provided evidence suggesting that disadvantaged populations can increase their intelligence through intervention. Studies have shown intelligence was similar for men and women in overall IQ scores, but the AP report indicated visual and spatial tasks were performed better by men and tasks involving verbal skills and perceptual skills were performed better by women. Evidence also suggests that girls and women suffer from social biases with regard to intelligence. For example, Bianco, Harris, Garrison-Wade, and Leech (2011) reported findings that suggest that teachers are less likely to recommend girls to gifted programs than boys. Studies have shown that stereotype threat influences racial and gender differences in standardized tests.

Future Directions

The future of genius research is likely connected to the future of intelligence research. Therefore, studies are likely to continue to investigate the role of the brain and its connection with IQ and genius, particularly if there are parts of the brain related to different intelligences. In addition, the theory of multiple intelligences as well as the role of culture in genius will likely be investigated. Future studies may also investigate how genius might be enhanced through medication, psychological, and even through technological interventions.

Mental Competency, Assessment of

H. Russell Searight

Lake Superior State University

Competence and Capacity: Definitions and Implications

Mental capacity, historically considered to be a core personality dimension vulnerable to disruption by mental illness (Moye, Marson, & Edelstein, 2013), is today viewed as a complex cognitive entity influenced by values, emotion, interpersonal relationships, and spirituality. Capacity was recently defined as: "...a professional clinical judgment as to whether an individual has the requisite minimal ability to successfully carry out a specific task (e.g. drive a car) or make a specific decision (e.g. refuse a medical treatment)" (Moye et. al., 2013; p. 3). The assessment of mental capacity has followed a similar trajectory from a simple unitary construct to a multifaceted, context-dependent ability set. Over the past 20 years, the distinction between capacity and competence has become blurred. Historically, "capacity" referred to the psychological domain of decision-making ability and judgment while "competence" referred to the legal determination that an individual was of "sound mind." However, this distinction has become less clear with civil courts now using the term "capacity" and psychologists referring to "capacity" and "competence" as essentially synonymous.

In contrast to other personality and cognitive dimensions, mental capacity has strong ties to state, federal and case law. Many of the formal capacity assessment measures were based upon or influenced by legal or applied ethical questions. An underlying reason for this ethical-legal dimension is that the findings of capacity assessments may lead to significant restrictions of individual autonomy such as being subjected to unwanted and invasive medical treatment, liberty-restricting psychiatric interventions, loss of control over personal finances, and the inability to drive or live independently

One issue on which there is clear agreement is that capacity is domain-specific. Global capacity determinations ("Does this patient have adequate capacity?" or "Is this patient competent?") are too broad to be legally, clinically, or practically useful. Specific capacities include medical decision-making, research participation, testamentary capability (making a will), financial management, parenting, and independent living These seemingly specific

domains have been further subdivided –for example, an individual in a relatively early stage of Alzheimer's disease may have the ability to manage a monthly spending allowance but not to make investment decisions.

Dimensions of Capacity

State statutes have outlined capacity parameters that have guided the development of clinical assessment strategies. Specific diagnoses such as aging-related neurocognitive disorders and schizophrenia, by themselves, are not an adequate basis for determining incompetence.

The initial dimension, *Communicating a Clear Choice*, typically becomes an issue when a patient either does not verbally communicate or a decision is not consistently communicated. This ability is a "threshold" criterion (Grisso & Appelbaum, 1998). If a consistent choice cannot be conveyed, such as when an individual repeatedly reverses a decision, incapacity is assumed. Under these circumstances, it is highly unlikely that the individual will be able to demonstrate the higher levels of reasoning associated with the other functional dimensions discussed below.

Understanding Relevant Information is not synonymous with short-term recall. An individual may be able to restate a description provided by a clinician or investigator but not be able to grasp its meaning. A useful informal strategy for assessing understanding is to ask the subject to describe the information previously provided in their own words. This dimension may also include knowledge of alternatives to proposed treatments or legal documents (e.g. living will versus durable power of attorney).

Appreciation reflects the ability to grasp information and apply it to one's own specific life circumstances. For example, in making judgments about testamentary capacity, individuals should demonstrate awareness of their own financial resources and property as well as the necessity of disposing of both upon the individual's death. In cases of a request for physician-assisted suicide, the patient should demonstrate a realistic understanding of their illness and its course as well as a recognition that death is irreversible and demonstrate awareness of relevant legal issues.

Reasoning requires active manipulation of the relevant information to arrive at a final decision. The process of decision-making is more important than the final choice itself. Patients may make decisions that may be unpopular with friends and relatives or that seem "irrational." However, the absence of external support for a particular decision does not mean that the patient's reasoning is automatically questionable. With respect to treatment options, including physician-assisted suicide or the choice to forego a treatment that might prolong the life of a terminally ill patient, the baseline requirement would be that the patient had an adequate comprehension of their condition and its prognosis with and without treatment.

Among mildly cognitively impaired elderly persons who wish to continue to drive, *Appreciation* and *Reasoning* would be met by the demonstrated ability to understand, in the abstract, the limitations that impaired short-term memory and concentration place on safe driving and then apply that information to their own particular condition (impaired sight, hearing, memory, etc.) and include this personally relevant information in their decision.

A patient who requests a formal driving evaluation or who discusses possible limitations to driving (e.g. only in daylight hours and driving restricted to two locations less than three miles from their home) would meet this standard. An elderly person who completely denied the possibility of driving-related sensory and cognitive limitations associated with aging would fail to meet criteria of adequate *Appreciation* and *Reasoning*.

The description above emphasizes features such as attention, concentration, memory and reasoning. However, many treatment or independent living decisions are based on non-cognitive factors such as emotion, religious beliefs, family dynamics, or cultural norms. It is well established that many seriously ill patients may prefer not to make medical treatment decisions and because of cultural norms that de-emphasize individual autonomy, choose to defer these judgments to close family members and/or the physician. In the context of adequate cognitive functioning, a choice to avoid receiving informed consent information related to medical treatment should generally be accepted.

Clinical Conditions Associated with Impaired Capacity

In terms of neuropsychological functions, reasoning, short-term memory, verbal knowledge and receptive language are most strongly associated with decision-making capacity by the middle stages of the illness. Alzheimer's disease (Appelbaum, 2007) and conditions such as Lewy body dementia, are likely to impair competence-related cognitive skills. Patients in the earlier stages of these illnesses and those with mild cognitive impairment (MCI) are likely to present a more ambiguous picture warranting detailed assessment. Delirium, associated with severe disruptions in consciousness, impairs attention and concentration to the extent that "holding" information in immediate memory to consider its implication, is often not possible. However, delirium is also frequently reversible and capacity questions should be deferred until the cause is addressed. Schizophrenia – particularly in its acute stage – is frequently associated with impaired capacity; bipolar mania often has similar effects (Appelbaum, 2007). The absence of insight into one's psychiatric illness will nearly always prevent individuals from meeting the *Appreciation* and *Reasoning* standards.

However, research suggests that diagnosis and functional abilities may be, at best, only moderately related. In addition to assessing clinical conditions, it is also important to consider the demands of the decision-making context and the consequences of the decision. For example, while someone with mild intellectual disability may not be able to provide an informed decision about the risks and benefits of cardiac bypass surgery, they may well be able to decide between two nursing home options. Additionally, as in the case of delirium, capacity may be fluctuating and periodic reassessment may be in order. This is particularly true with patients who have acute psychiatric illnesses or are confused due to systemic medical illness and or medication side effects.

Instruments for Capacity Assessment

Among formal, psychometrically sound assessment tools, the most widely used clinical measure in medical and psychiatric settings for assessing capacity for independent living,

and medical decision-making, is the Mini Mental State Exam (MMSE) developed by Folstein and colleagues. Composed of questions assessing immediate and short-term recall, attention and concentration, numerical computation, language expression and comprehension as well as visuopractic abilities, the MMSE has established overall norms as well as age- and education-specific norms. With a total of 30 possible points and a standard cut off score of below 24 indicating impairment, persons with high scores have been found to have intact medical decisional capacity with scores below 20 typically indicating impairment. Despite its efficiency in assessing a range of basic cognitive functions, the MMSE has several limitations. Scores between 20 and 24 do not clearly indicate the presence or absence of capacity. Additionally, the MMSE does not directly address the core dimensions involved in medical treatment choices, testamentary abilities, or one's ability to live independently.

Two scales developed for use in primary health care settings assess patients' knowledge of the elements of informed consent for medical treatment. The Hopkins Competency Assessment Test (HCAT; Janofsky, McCarthy & Folstein, 1992) has three versions based upon reading level (grades 6, 8, or 13). After reading four paragraphs describing the dimensions of informed consent, information about how clinical conditions could disrupt decision-making and advance directives, the patient then takes a brief quiz covering the material. While the HCAT asks generic questions, the Aid to Capacity Evaluation (ACE; Etchells, Darzin, Silberfeld, et al., 1999) is a template of questions – the content is filled in based on the patient's specific medical condition or the treatment decision being faced. Questions reflect the basic elements of informed consent, possible consequences of the patient's decision and how psychiatric disorders could influence decision-making.

Capacity for independent living has been evaluated with several standardized scales. The Independent Living Scale (ILS), administered in a structured interview format, has five subscales –Memory Orientation, Managing Money, Managing Home and Transportation, Health and Safety, and Social Adjustment. ILS performance has been found to differentiate persons with schizophrenia requiring different levels of supervision for community living. While the ILS is administered directly to the patient, the Bristol Activities of Daily Living Scale (BADLS; Bucks, Ashworth, Wilcock, & Siegfried, 1996) questions the caregiver. Each item is rated on a scale from 0–2 depending on the level of assistance required for a specific task. Dimensions include self-care such as bathing, dressing, and hygiene as well as housework, finances and transport. In a sample of home dwelling individuals with dementia, the BADLS was found to be significantly and strongly correlated with the MMSE.

Capacity for consent to participate in clinical research has also been the focus of multiple assessment instruments. The Deaconess Informed Consent Comprehension Test (DICCT) was developed to assess subjects' understanding of their participation in clinical drug trials. In contrast to assessing the elements of informed consent for treatment, the DICCT includes questions specific to research such as the possibility of receiving a placebo and the distinction between individualized treatment and investigating new medications without clearly established efficacy. The DICCT is in a template format so that specific medications, their side effects, etc., can be inserted. In initial research, it was found that the average score was 70% with study participants over-estimating their understanding of the trial; medication side effect information was least likely to be retained (Miller, et al., 1996).

The Wechsler Memory Scale (WMS-IV)

Caitlin Dzikon

Bastyr University

The Wechsler Memory Scale (WMS-IV) (2009) is a test that is designed to evaluate auditory, visual, and working memory in people 16–90 years old. There are numerous psychiatric and neurological conditions for which memory impairment is a key symptom, and memory also has a strong influence on our social interactions and daily behavior. Thus, assessment of memory is an important aspect of understanding ourselves and others and the WMS-IV is the most valid, reliable, and comprehensive test available for this today though it has been updated over time, as our knowledge about the nature of memory has grown.

David Wechsler (1945) developed the original version of the test after noting that assessment of memory capability was often part of the psychological evaluation in mental hospitals. His stated goal in was to provide a test that allowed "rapid, simple, and practical memory evaluation" (Wechsler, 1945). This original version of the test included seven subtests: a visual memory subtest, several auditory memory measures, and what would now be considered simple attention tasks such as counting by threes. It took 15–30 minutes to administer and resulted in a single score called the memory quotient. An individual's memory quotient could be compared to normative data that Wechsler derived from 200 patients between the ages of 20–50 at Bellevue hospital. For people outside of this age range, normative comparisons could be extrapolated.

The original version was widely criticized. One criticism was that the sample from which the norms were developed was inadequate and many felt the nature of memory made it inappropriate to extrapolate norms for older and younger patients. Critics also believed that the test placed too much emphasis on verbal material and made it difficult to differentiate between visual memory and visuomotor difficulties. Many psychologists also felt that the single memory quotient score did not capture the true nature and complexity of memory functioning. Nevertheless, this version was extensively used for clinical practice and research and was even translated into other languages, highlighting the strong need that existed for a tool to evaluate memory.

During the 1960s and 1970s, our understanding about the nature of memory expanded which brought further questions about the way the test was designed. Specifically, new

research showed several subcomponents of memory such as verbal and visual memory and suggested the different types were localized to different parts of the brain. An increasing number of studies also showed evidence of both an immediate and a long-term memory. Given this, Elbert Russell, a neuropsychologist working within the Veterans Administration System, argued that a test was needed to assess these different aspects of memory in order to improve the ability to evaluate the impact of brain damage. Russell developed a new test he titled the Wechsler Memory Scale, Revised (WMS-R; Russell, 1975) and included two of the original subtests, a story recall, and a visual recall of information drawn by the examinee. He also added a "delay condition" to each task which involved assessment of the amount of information retained after 30 minutes spent engaged in distracting activities. Normative data for this version was gathered from 75 patients with brain damage and 30 controls without brain damage. Russell's version was lauded for its ability to differentiate between verbal and visual memory and for having the delay condition. There were concerns, however, about the psychometric properties and criticism about the normative sample since it primarily consisted of brain damaged males. Nonetheless, Russell's WMS-R remained popular and was frequently used until 1987 when another version of Wechsler's test was published.

The publisher used the title, "Wechsler Memory Scale, Revised" for their first revision of Wechsler's scale which led to confusion since Russell's version had the same title; it was sometimes unclear in the literature which test was being referred to. However, Russell did not produce additional versions and, over time, Wechsler's tests gained popularity and eventually became the standard in assessment of memory. This popularity began with Wechsler's WMS-R which included more subtests, delayed memory conditions, and an expanded normative population.

The normative data for Wechsler's second edition was gathered from 316 people aged 16–74 and the sample was closely aligned with the census data of 1980 in terms of diversity. It included eight subtests including delayed recall measures as well as more tests that assessed visual memory and a test of concentration. Changes were also made to the scoring system to offer more precise criteria and to allow for computation of scores for each aspect of memory rather than a singular memory quotient; this improved the reliability of the test across examiners. Concerns were noted about this version; for instance several of the visual memory tasks appeared to require multiple cognitive abilities and some were noted to assess attention rather than vision. The test also did not easily differentiate people at the extreme ends of the scoring continuum, suggesting the test may not have been able to fully capture how high or low some individuals could have scored. Critics also noted that the test had no way to assess recognition memory. Nevertheless, the test was the most comprehensive assessment of memory available and was used widely for the next 10 years.

The advice of users was sought in developing the third edition of the Wechsler Memory Scale, the WMS-III, which was published in 1997. This version included six subtests that took approximately 45 minutes to administer as well as several optional tests the examiner could use when additional information was needed. The scoring system continued to advance, allowing for computation of overall memory, immediate and delayed memory, working memory, and recognition for both auditory and visual content. In addition, you could compute scores that measured learning slope and the amount of information retained from an initial trial. Scores could be interpreted by comparing them to normative data

gathered from over 1,000 people who ranged in age from 16–89. The normative sample for the WMS-III was also the sample used for the third edition of the Wechsler Scale of Intelligence, allowing for comparison of different cognitive abilities. This version was praised for its increased reliability, inclusion of subtests that allowed for differentiation between psychomotor and visual memory difficulties, as well as the addition of more visual memory tasks. The ability to assess recognition improved treatment planning by distinguishing between encoding and retrieval impairment.

Weaknesses in the third version emerged through extensive use of the test as well as knowledge of the brain based on new technology. One of the visual subtests was sensitive to people with social perception impairments but did not adequately assess visual memory in other people. Another visual subtest was often confusing to older adults and appeared biased against certain cultural groups. The norms were also criticized as questions arose about fatigue since the sample was taking both the WMS and the WAIS. There were also concerns that the sample contained people with undiagnosed dementia, reducing the sensitivity of the test to detect memory impairment. An abbreviated edition, WMS-IIIA, was released in 2002 to decrease testing time; however the content and related concerns were the same, so it was not widely adopted.

The development of the Wechsler Memory Scale-IV (WMS-IV) was the most detailed and comprehensive to date. It was informed by surveys of users and a panel of memory assessment experts and included reviews of the psychometric properties and content. WMS-IV includes seven subtests for individuals ages 16–69 and a five-subtest version for ages 65–90. The normative sample included 1,400 people pre-screened for average IQ and no cognitive impairment; additionally, each age group was fully sampled and representative of the population in age, sex, race/ethnicity, education level, and geographic region. The WMS-IV has improved validity and reliability, reduced ability of examinees to guess correct answers, and an improved ceiling and floor for each subtest. Its visual subtests require processing of both spatial and detail elements as brain studies have revealed each is processed differently. All subtests were designed to be fair across cultural groups. Scores that can be generated from the WMS-IV include index scores for auditory, visual, visual working, immediate, and delayed memory; each index score is composed of at least two subtests. The WMS-IV also provides contrast scores which allow the examiner to obtain information about performance in one area adjusted for performance in another area. The WMS-IV works with the WAIS-IV to allow for a full assessment of all cognitive abilities that might influence memory. The WMS-IV has been widely accepted and used frequently in research and clinical settings alike, thus maintaining its status as the best tool for evaluation of memory.

The evaluation of memory is extremely important for conditions like schizophrenia, major depressive disorder, dissociative disorders, posttraumatic stress disorder, and learning disorders all of which include disruption of memory as a criterion. Differentiation between similar medical conditions, such as different types of dementia, also requires assessment of memory to determine the pattern of memory impairment and subsequent appropriate treatment. Evaluation of memory is also important after traumatic brain injury and demyelinating conditions as it impacts driving ability, financial management, and other independent living issues. For people without a disorder or illness, memory is still an important factor in daily lives. For instance, memory impacts what we recall after a social encounter which influences what we think about others, our decisions about whether we

want to interact with someone again, and our behaviors when we interact with the same person again. Overall, memory assessment is a valuable tool and the WMS-IV is the most comprehensive tool available for this. It is likely to continue to evolve as our understanding of the brain and memory continues to grow.

Anne Anastasi

Constance A. Sztukowski-Crowley

Port St. Lucie, FL

Brief Overview

Anne Anastasi was born in Manhattan, New York in 1908. She was raised in an uncommon family – both in structure and convention. Her family was a first-generation Sicilian family that prized education but spurned most of their neighbors, viewing them as beneath their standing. This shaped Anne to become an ambitious yet independent scholar, albeit with a tendency to being absent-minded and possessing gaps in the area of common knowledge (such as not putting metal letter openers in electrical outlets). By the 1950s, Anne Anastasi was a well-known expert in the field of assessment and psychometrics. Her wide-ranging research encompassed the psychological aspects of creativity, statistical issues, basic research and techniques, trait formation, and individual differences, as well as the misuse of tests and culture fairness in testing. To this day she is referred to as the "Test Guru," and significantly impacted the field's understanding of psychological testing. During her lifetime, Anastasi published more than 150 scholarly books, monographs, and articles. Her books became classics and are still extensively used throughout the world. In addition to *Differential Psychology and Psychological Testing*, Anastasi's other major publications included *Fields of Applied Psychology* (1964); *Individual Differences* (1965); *Testing Problems in Perspective* (1966); and *The Gap between Experimental and Psychometric Orientation* (1991). Just a few of her honors include that she was president of the American Psychological Association (APA) and was awarded multiple honorary degrees as well as the National Medal of Science by President Reagan. She is possibly the most prominent woman in psychology during the latter half of the twentieth century.

Her Early Years

The family she was born into and the way that she was raised had a significant impact on Anne's development, interests, and personality. To understand Anne, it is helpful to get a

sense of what her early years and her family of origin were like. In 1904, Teresa Gaudiosi, who was then about 19, immigrated from Sicily to Manhattan, New York along with her mother, Maria, and her younger brother, Pasquale. They were an educated family, and Maria held her family somewhat apart and superior to those that lived around them, stating that they were "surrounded by peasants." A few years after their arrival, on August 22, 1907, Teresa, who worked as a teacher at the time, married Antonino Anastasi, who worked for the New York City Board of Education as a Truant Officer. It was into this context that Anne Anastasi was born on December 19, 1908. However, Anne was to never know her father or her father's family. Antonino died just a year after Anne was born, on January 6, 1910. Following his death, Teresa became estranged from Antonino's family of origin whereby Anne never did know that part of her heritage. While at this time it was unusual for a woman to raise a child without the support of a father, Teresa did so by being a part of an uncommon family configuration – her maternal grandmother was the matriarch, her mother was the family bread winner, and her maternal uncle was her father figure. It is these three individuals who shaped the direction of Anne's life.

While Teresa Anastasi and Pasquale Gaudiosi were highly educated, that education focused on the classics and humanities, and they were not prepared for self-sufficiency. Still, she was a resourceful and determined woman. Teresa's first attempt at providing for the family financially was when she taught herself bookkeeping. She and Pasquale then founded a piano company. When this endeavor eventually failed, Teresa held various other jobs until she finally landed a position as office manager for one of the largest foreign newspapers in the New York City area, *Il progresso Italo-Americano*. She held this position until she retired. Although Teresa was very focused on providing financially for the unique family, she never failed to give Anne the love and attention she wanted. Regardless of how tired Teresa was, she always took time to play role-play games and word games with Anne.

While Teresa provided financially, and Pasquale offered Anne a positive male role model, it was matriarch Maria that took charge of Anne's education. She limited Anne's contact with other children and considered them boisterous and socially beneath the Gaudiosi family. She provided her with a strong education balanced by a broad range of academics and sprinkling in experiences from her own girlhood. Their study sessions were interactive and Anne found them exciting and glamorous. A public school teacher, Dora Ireland, was also hired to provide Anne with lessons every afternoon. Dora encouraged Maria to send Anne to public school, but these suggestions were ignored for the first several years. When Anne was nine, Dora's pleas were finally heard. Anne was to attend third grade in a public school, provided it was the school where Dora worked, and Dora was to escort Anne to and from school every day.

Unfortunately, this experience was not one of the most positive moments of Anne's life. In only two months she was skipped to fourth grade. This caused a variety of problems to arise when Anne was given a seat at the back of the classroom. She was not only somewhat overwhelmed by the crowed and noisy conditions of her classroom, but on top of this, it was discovered that Anne was having difficulty seeing the board. Once it was determined that Anne required glasses, she resumed studies at home and did not return to school until the next fall when she entered the sixth grade at a school in the Bronx. At the end of that year, 11-year- old Anne graduated sixth grade from P.S. 33 at the top of her class and began the accumulation of her many awards with a gold medal for academic excellence.

   The following fall, Anne entered Evander Childs High School but quickly became dissatisfied. The school was again overcrowded, and Anne felt that she was not being intellectually challenged. At the suggestion of a friend, Anne dropped out of high school and attended Rhodes Preparatory School in Manhattan (which was primarily attended by adults preparing to enter college) for two years. At the age of 15, Anne entered Barnard College.

   Anne was very interested in mathematics, having taught herself spherical trigonometry as a teen, and so when she initially enrolled at Barnard, she intended to major in math. However, as a sophomore, she attended a psychology class taught by Harry Hollingworth and read an article on correlation coefficients authored by Charles Spearman, resulting in her shifting focus to psychology. Spearman's work had allowed Anne to realize that she could pursue psychology while not abandoning her love for math. During her junior year, Anne was a student in the psychology honors program and attended graduate courses at Columbia University. It was during this time, when Anne was 18 to 19 years old, that she co-authored her first journal article on aesthetic preferences (Lund & Anastasi, 1928). In 1928, Anne Marie Anastasi earned her Bachelor of Arts from Barnard College. At graduation, Anne was elected to Phi Beta Kappa, and earned the prestigious Caroline Duror Memorial Graduate Fellowship that was awarded each year for the graduate showing the most promise for distinction in her chosen field. (This was an annual award of $600, which would be valued at over $8,000 today.) In the fall of 1928, Anne entered Columbia University and proceeded directly to the PhD track as she had already taken a number of graduate classes in psychology, thus bypassing the need to first earn her Master's degree. She completed her graduate work in the field of differential psychology – the area of study that explores individual and group differences in behavior – and received her PhD in 1930.

   The summer following her graduation from Barnard, Anne went on to enroll in a summer class with Dr. A. T. Poffenberger, who was head of the Department of Psychology at Columbia University. She followed this with courses during her first year with several significant psychologists. Among these notable psychologists was Robert Woodworth, who wrote a text titled *Experimental Psychology*. This text was highly influential and was called the Columbia Bible, with some scholars viewing it as the Bible for North American psychology. Carl Warden was also influential in Anne's education. He is best known for his work on comparative psychology and his texts, such as *Evolution of Human Behavior* (1932) and *The Emergence of Human Society* (1936). Gardner Murphy is another among the significant figures of Anastasi's professional education. Murphy is probably best known for his experiments in the field of parapsychology and the development of his biosocial theory of personality. He contributed much to our understanding of learning, comparative, and physiological psychology. H. E. Garrett (who later was to become her dissertation mentor) was one of the most prominent of the era's segregation psychologists. He also contributed significantly to the field with his text on experimental psychology and his work regarding statistics in psychology and education. This was the focus that Anne had pursued since she read Spearman's article on correlation coefficients. It was during this time, referred to as the "Golden Years" of Columbia University's psychology department, that Anne began her professional studies.

   In her oral history, Anne describes the summer of 1929 as pivotal in her career development. During this summer there were three unrelated but highly memorable events. First,

Anne received a summer research assistantship with Charles B. Davenport. While at the Carnegie Institution of Washington in Cold Harbor on Long Island, Anne assisted Dr. Davenport in creating culture-free tests. The second major event was taking courses with and the establishment of lifelong friendships with Clark Hull and R. M. Elliot. Finally, it was during this summer that Anne attended the International Congress of Psychology at Yale which was the first to be held in the United States (Fish, 1983).

Her second year of graduate school was filled with courses for her specialization. Otto Klineberg had just returned from Europe where he had been gathering comparative data on test performance. It was with him that Anne studied racial differences. She also took a course at Randall's Island Children's Hospital on intelligence testing. Anne also enrolled in courses at Columbia Medical Center and College of Physicians and Surgeons in the areas of neuroanatomy and neurophysiology. She also time spent on completing her dissertation on a group factor identified in immediate memory for rote learning (Anastasi, 1930).

Marriage and Career

During graduate school she also met John Porrter Foley, Jr., a fellow Psychology PhD student at Columbia University. Foley was known for his early work on conditioned responses in primates and abnormal behavior in humans. Later, he became known for his work in industrial psychology. Foley's work also included collaborations on testing research with his wife. While Foley's and Anastasi's interest in psychology was shared, their collaboration in Foley's experiences and interests influenced and broadened Anne's thinking, particularly in the areas of animal and comparative psychology. His work with J. R. Kantor (known for the development of interbehaviorism – a naturalistic system in psychology) and Franz Boas (an anthropologist) as well as his increasing interest in the area of industrial psychology also had an influence on Dr. Anastasi. On July 26, 1933, Anne Anastasi and John Porter Foley, Jr. married following a courtship that began while they were both pursuing their PhDs in Psychology from Columbia University. Anne was said to have noted that her marriage gave her the benefit of two psychology PhDs.

About a year after her marriage to Foley, Anne was diagnosed with cervical cancer. While radium therapy eradicated the cancer, it also destroyed her chances of bearing children. However, Anne felt that this was at least partially responsible for her academic and career success as it allowed her to remain childless without having to suffer conflict or guilt about her state. A lifelong friend of Anastasi, Agnes N. O'Connell (2002), quotes Anne as saying, "response to misfortune can vary from self-pity, depression, and even suicide, to enhanced motivation and a determination to show the world that it can't keep you down." Anne clearly chose the route of enhanced motivation.

Because universities were reluctant to hire husband and wife for the same department, Anastasi taught at Bernard College, while Foley taught at George Washington University in Washington DC. As a result, the early years of their marriage were characterized by distance and long hours of travel. Eventually, Foley obtained a position with the Psychological Corporation in New York City, and the couple were able to remain together thereafter.

Anne began at Bernard College in 1930 as an instructor of psychology and earned $2,400 that first year. This would be about $32,700 at today's value. In 1939, Anne moved to Queen's College of the City University of New York. She served there as assistant professor and department chair until 1946 when two-thirds of the department, including Anne, left due to difficulties in being allowed to teach and research.

In 1946, Anne found her final academic home at Fordham University, in the Bronx, with the Graduate School of Arts and Sciences. She was made associate professor in 1947 and full professor in 1951. Anastasi served as department chair from 1968–1974. She retired from there in 1979 when she became professor emeritus. She continued to be active professionally until her death in 2001.

Major Contributions and Achievements

Anne was noted for both her brilliance and her absentmindedness. She had multiple major publications, was an exceptional teacher and mentor, yet was distracted by the more practical side of life. In *The New York Times* obituary, Erica Goode reported a quote from Dr. Mary Procidano (the current chair). "Once, Dr. Procidano said, she heard a shriek coming from Dr. Anastasi's office. Running to see what was wrong, she found Dr. Anastasi trying to pry a plug out of an electrical outlet by using a metal letter opener. When Dr. Procidano asked her if she got a shock, with the letter opener still in her hand, Anastasi replied, saying 'How fascinating. How did you know it was a shock?'"

Among Anastasi's professional honors she received the APA Distinguished Scientific Award in 1971, the Recipient award for distinguished service to measurement from the Educational Testing Service (ETS) in 1977, was recognized for distinguished contribution to research by the American Educational Research Association in 1983, the APA E. L. Thorndike Medal in 1983, the Gold Medal for lifetime achievement from the American Psychological Foundation in 1984, and the James McKeen Cattell fellow of the American Psychological Society in 1993.

She also held several leadership roles. In 1946 she was elected to the presidency of the Eastern Psychological Association and later served both the Psychonomic Society and the APA on the board of directors, in addition to her role as APA president. Anastasi received honorary doctorates from La Salle University in Philadelphia, the University of Windsor, Canada, Villanova University, Cedar Crest College, and Fordham. She was a member of the honor societies of Phi Beta Kappa and Sigma Xi. In the Spring 1987 issue of *Psychotherapy in Private Practice* Eileen A. Gavin reported the findings of a study of the world's most prominent women psychologists. Anne was first among 84 possible choices.

Research

While Anastasi's research followed a number of major themes, with a major contributing focus on the nature and measurement of psychological traits, the range of her individual papers is astonishingly wide. Among the other research topics she engaged in was language development among black and Puerto Rican children, published in 1950. She carried this

general theme of the effect of experience on traits into publications on intelligence and family size, age changes in adult test performance, and attitude differences between males and females. A further focus on her writing and research has been test construction, evaluation, and interpretation, ranging from conceptual and statistical questions to misuse and misinterpretation. Many of these continue to be issues today.

Being known as the "Test Guru," she also had a number of written publications on different types of test issues including test bias, speeded tests, item selection, coaching for tests, culture-free, and culture-fair tests. In addition, with her husband, she contributed to various psychological aspects of art. They studied cultural differences in artistic expression, abnormality of art, art by adult psychotics, and the appropriateness of projective tests such as Draw-a-Person and House-Tree-Person in clinical assessment. Some of Anastasi's isolated studies included the effect of shape on the estimation of area, methodological controls of the diary method, a study of fear and anger among college students, a factor analysis on the performance of dogs on learning tests, and a case study of a musically gifted "Idiot savant."

Heredity and Environment

The basic premise of all of Anastasi's experimental and theoretical work was that human beings, for a variety of reasons, were different from one another. In the preface to her 1937 premiere text, Anne states, "Man has always been aware of differences among his fellow-beings. He has, to be sure, entertained various theories, beliefs, or superstitions regarding the causes of such differences, and has interpreted them differently according to his own traditional background, but has at all times accepted the fact of their existence." From this foundational concept, Anne influenced generations of professionals in their approach to testing methods.

In 1957, as part of a presidential address to the APA, Anastasi noted that the heredity/environment controversy (also known as nature versus nature), while generally accepted as settled, could not be resolved on the basis of current research, which she felt was decidedly inconclusive. Instead, Anne presented what she felt was a more viable hypothesis: that heredity and environment were not additive factors in determining character, but instead personality was more likely the result of the interaction of the two components.

As early as her first book in 1937, Anastasi had identified two myths upon which much of the understanding of that time was based: (1) inheritance is indicated only by resemblance to parents or immediate ancestors, and (2) hereditary factors that influence structure mean a particular behavior will occur. Anne recognized that individuals often bore resemblance, both physically and characteristically, to extended family (such as a child bearing the same red hair that was last manifested by a great-grandparent). She also recognized that while certain physical characteristics, such as long legs, may aid in becoming a talented hurdler, the presence of long legs in and of itself will not result in that outcome. Anastasi, always looking to research data, recognized at least four other factors that came into play: (1) prenatal environment, (2) experimentally produced variations in behavior, (3) human children reared in abnormal environments, and (4) differences among social or occupational groups.

Noting that her contemporaries had been perhaps asking the wrong question when it came to heredity and environment, Anastasi observed:

> The traditional questions about heredity and environment may be intrinsically unanswerable. Psychologists began by asking *which* type of factor, hereditary or environmental, is responsible for individual differences in a given trait. Later, they tried to discover *How much* of the variance was attributable to heredity and how much to environment. It is the primary contention of this paper that a more fruitful approach is to be found in the question, *'How?'*

Anne used phenylpyruvic amentia (phenylketonuria) and amaurotic idiocy (Tay-Sachs disease) to explain that some heritable conditions were isolated from any environmental influences. (At the time, both of these conditions were considered irreversible congenital defects.) While other conditions, such as hereditary deafness, would initially cause intellectual lags, these would not remain once adaptations had occurred. Furthermore, Anastasi pointed out that individuals might display susceptibility to inherited factors that were then triggered by environmental factors (such as in the diathesis stress model). The most important point, for Anne, in this argument is that any influence heredity had on psychological traits was indirect. "Psychological traits are related to genes by highly indirect and devious routes," she emphasized.

Another salient point for Anastasi was that environmental variations could be either organic or behavioral, and organic variants would resemble hereditary factors. These factors could be set along a continuum of how much they directly or indirectly affected behavior. Behavioral alternatives were considered to have a direct influence on behavior while those considered organic were of an indirect relationship. As an indirect influence from an organic cause, Anne used the stereotypical "blondes have more fun," while the direct environmental factor was exemplified by social class membership. Anne further clarified by stating, "There is clearly a need for identifying explicitly the etiological mechanism whereby any given hereditary or environmental condition ultimately leads to a behavioral characteristic – in other words, the 'how' of heredity and environment."

Psychometrics

The area for which Anastasi is most well-known is psychometrics. Psychometrics is the field of study concerned with the theory and technique of psychological measurement. She felt that psychologists were having difficulty staying focused on the reason for psychometrics rather than becoming absorbed by the construction of the test. Anne began her 1991 article, "The Gap between Experimental and Psychometric Orientations," stating that

> One of the inevitable consequences of the rapid growth of psychology is an increasing specialization in the training and functioning of psychologists. Specialization is obviously needed ... At the same time, specialization creates ...the danger that the

methodological focus becomes too circumscribed to provide an adequate picture of so complex a phenomenon as human behavior. As a result, one's data may be incomplete and one's conclusions incorrect.

Anne felt that the scientists were becoming so focused on the development of the test and the technique, that the very reason for the test was becoming lost.

Another point made by Anastasi was that initially experimental psychologists ignored random variability because it was seen as "error" and would therefore restrict how the general findings might be used. Because these early experimental psychologists ignored any form of random variability, Anne felt that they were simply exploring general cases of human behavior and did not learn anything specific to real, individual human differences in behavior.

Anne and other psychometricians, on the other hand, consider any variance, not as error but as crucial to the investigation of human behavior. All facts, including all sources of variance, and the overall measure of variability (standard deviation) are inextricably linked in our analysis of the findings. Part of this analysis includes seeking the full range of human variability for the behavior under question. By realizing that the standard deviation covers the middle 95% of group behavior, we have one avenue for analyzing individual differences. Including an awareness of the correlation coefficient (how closely two variables fluctuate together) gives us additional information. Together these two tests give us a more complete picture of how an individual's behavior compares to the group, and how individual behavioral factors within the person fill out that picture.

Closely linked to these issues, according to Anastasi, is experimental design. Anne lists three key aspects linking statistical methodology and experimental design: (1) Analysis of Variance (ANOVA), (2) Structural Equation Modeling (SEM), and (3) Factor Analysis. Each of these approaches gives us a more complete picture of the variability and differences both within and between individuals. ANOVA allows us to study simultaneously the effects of several independent variables. Factor analysis creates a different lens for understanding. For example, how do gender, musical talent, and handedness affect mathematical ability? Does only one of these main factors come into play? Two? An interaction between one or more variables? Or does one factor, say handedness, only seem to affect mathematical ability if musical talent is first taken into consideration? The final link between statistics and experimental design, SEM, takes our understanding of variables and their impact even farther. SEM tests theoretical models (assumptions explaining *how* the data was generated) using hypothesis testing to develop our understanding of the complex relationships among constructs (any complex psychological concept, such as fear, motivation, personality, etc.).

Ann felt that when dealing with human behavior these two aspects, variability and experimental design, were of vital importance. You could not ignore variability or you were liable to come to false conclusions. At the same time, you could not become totally immersed in the statistics and ignore the psychological content and context of human behavior. Each aspect depends upon the other for informative operation in research design, in data analysis, and in the interpretation of the results.

Intelligence

Another area where Anastasi had extraordinary impact was with the concept of intelligence. In a time that many individuals considered intelligence fixed past about age 12, and defined by a single number, Anne saw things differently. "Intelligence is not a single, unitary ability, but rather a composite of several functions. The term denotes that combination of abilities required for survival and advancement within a particular culture" (Anastasi, 1992, p. 613). Of particular note here is Anne's focus on intelligence as a function of culture.

Anastasi believed that most references to culture-free and culture-fair tests were erroneous and was adamant that culture-free tests were impossible to design. Most of our current intelligence tests measure success in an academic environment and not success in the individual's cultural environment. Anne asserted that while this use of a test was valid, an intelligence test that measured how well individuals have acquired skills and knowledge valued in their own culture should be developed.

Much of her research emphasized what intelligence tests should and should not be used for, and cautioned against the misuse and misinterpretation of test results. She stressed that intelligence (not just the scores) changes over time and that intelligence can improve with experience. Anastasi wrote that tests can serve a predictive function only insofar as they indicate to what extent the individual has acquired the prerequisite skills and knowledge for a designated criterion performance. What persons can accomplish in the future depends not only on their present intellectual status, as assessed by the test, but on their subsequent experience. She pointed out that intelligence tests can be used for three things:

1) They permit a direct assessment of prerequisite intellectual skills demanded by many important tasks in our culture.
2) They assess availability of a relevant store of knowledge or content also prerequisite for many educational and occupational tasks.
3) They provide an indirect index of the extent to which the individual has developed effective learning strategies, problem-solving techniques and work habits and utilized them in the past.

Jens B. Asendorpf

John F. Rauthmann

Universität zu Lübeck

Jens B. Asendorpf (born October 26, 1950 in Marburg, Germany), emeritus professor at the Humboldt-Universität zu Berlin (Germany), is an influential personality psychologist. He first studied mathematics and computer science (1969–1973; University of Kiel and Technical University of Berlin) and then also psychology (1973–1978; University of Marburg and University of Giessen). Asendorpf received his doctorate in psychology from the University of Giessen (1981) under Klaus R. Scherer and was a visiting scholar at Yale University while still a graduate student. He then worked with Franz E. Weinert on a longitudinal study of personality development from age 4 onwards (LOGIC) at the former Max Planck Institute for Psychological Research in Munich (1981–1994). From 1994 to 2014, Asendorpf assumed the role of full professor for personality psychology at the Humboldt-Universität zu Berlin. He has been head of department (2008–2010), president of the European Association for Personality Psychology (EAPP; 2010–2012), served as an editor for prestigious journals (e.g. *European Journal of Personality*), and is on numerous editorial boards (e.g. *Journal of Personality and Social Psychology* since 2008).

Asendorpf has been, and still is, very prolific, having published more than 120 articles, 10 books, and 85 chapters. His papers appear in the most prestigious psychological journals (e.g. *Journal of Personality and Social Psychology*, *Developmental Psychology*, *Child Development*) and have been widely cited (14,509 citations, with an *h*-index of 59 as of June 28, 2017 on Google Scholar). Moreover, he has written one of the definitive German textbooks of personality psychology (*Psychologie der Persönlichkeit*), published by Springer, and contributed to the recognition of behavior genetics in Germany by continuously publishing chapters on this topic in German psychological and sociological handbooks and textbooks. He also was among the first to alert personality psychologists to the replicability problem (Asendorpf et al., 2013). Asendorpf has received numerous grants, collaborated with researchers around the world, and conducted high-profile research throughout his career. To recognize his outstanding career, he has received the prestigious Life-Time Achievement Award from the EAPP.

Asendorpf's contributions to personality psychology are manifold. He is flexible and diverse in his research interests which can be roughly segmented in having contributed important insights into (1) non-verbal expressiveness (1979–1983); (2) personality development, including continuation of the LOGIC study until age 29 (1982–ongoing); (3) social interactions and shyness in children and adults (1984–1994); (4) temporal consistency and continuity of personality (1992–1994); (5) couple relationships and attachment (1994–ongoing); (6) personality types versus personality traits (2001–2006); (7) implicit measures in personality assessment (2006–2015); and (8) development of immigrant versus non-immigrant adolescents (2006-ongoing). Generally, he has always maintained a particularly keen interest in social relationships (e.g. shyness, inhibition, attachment, sexual and romantic relations, social support, social competencies), personality development (e.g. continuity of traits; inter-individual differences in intra-individual stability; developmental trajectories across the life span), multi-method data (e.g. physiological measures, observation data, self-reports, informant-reports, implicit measures), as well as advanced statistical analyses (e.g. multi-level modeling).

Asendorpf pioneered multi-method approaches to personality assessment by being one of the first European researchers to fruitfully combine systematic behavior observation in the laboratory *and* field with informant- and self-reports. With this methodology he was able to develop an influential two-factor model of social inhibition from childhood to young adulthood (e.g. Asendorpf, 1989; Asendorpf et al., 2008). Later, he also included implicit association tasks into his methodological repertoire. For example, he demonstrated how explicit and implicit self-concepts influence controlled and spontaneous behavior in social situations, respectively (Asendorpf et al., 2002). Further, Asendorpf routinely employed longitudinal multi-method data to answer questions on personality development. For example, in the Berlin Relationship Study, which he initiated, he examined to what extent personality traits form relationships and vice versa across time (Asendorpf & Wilpers, 1998). His interest in social relationships, development, and multi-method data culminated in several newer, highly influential projects and papers, such as (1) an evolutionarily informed account of human sociosexuality (Penke & Asendorpf, 2008), (2) the Berlin Speed Dating Paradigm to examine the course from dating to mating to relating (Asendorpf et al. 2011), (3) distance regulation in partner relationships (Hagemeyer et al., 2015), and (4) acculturation processes (Reitz et al., 2016).

In all of his studies, Asendorpf has demonstrated outstanding methodological rigor and statistical acumen. The content, quality, and quantity of his research have thus brought Asendorpf into prominence and position him as one of the most influential personality psychologists of our time.

James N. Butcher

Dong Xie and Cory L. Cobb

University of Central Arkansas

James N. Butcher is a leading psychologist in personality assessment. He is best known for his significant contributions to research and clinical application of the Minnesota Multiphasic Personality Inventory (MMPI), its revised edition (MMPI-2), and its adolescent edition (MMPI-A). Throughout his professional career in psychology, Butcher has authored 60 books and more than 250 articles covering a large range of topics including: MMPI/MMPI-2/MMPI-A, cross-cultural translation and adaptation of personality assessment, computer-based personality assessment, and abnormal psychology. Butcher has conducted numerous workshops on MMPI/MMPI-2/MMPI-A and trained thousands of professionals in the use of these instruments, both domestically and internationally.

Education

Butcher graduated from Guilford College in North Carolina with a BA in psychology in 1960. He received his MA in experimental psychology in 1962 and his PhD in clinical psychology in 1964 from the University of North Carolina at Chapel Hill. Since then, he served on the faculty of the Department of Psychology at University of Minnesota for nearly 40 years till his retirement in 2003.

Scholarly Accomplishments and Contributions

One specific area of accomplishments Butcher has made is research on and application of the MMPI/MMPI-2/MMPI-A, which were covered by many of his books and articles. Butcher's first book on the MMPI, *MMPI: Research Developments and Clinical Applications,* was published in 1969, and his most recent book (with Hass, Greene, and Nelson), *Using the MMPI-2 in Forensic Assessment*, was published in 2015 by the American Psychological Association (APA). These books, along with numerous others in between, identified needs

and trends, summarized empirical findings, and provided guidance for the use of MMPI instruments across various settings, nations, languages, and ethnicities.

Butcher's initial work on the MMPI began with a teaching assignment of a course on MMPI during his second year as faculty at the University of Minnesota. He was surprised to find that the research at Minnesota was rather sparse due to two historical figures of MMPI (Starke Hathaway and Paul Meehl) moving to other areas of research. Butcher soon identified the need to reactivate attention to the MMPI. He established an open forum on the MMPI and organized the first *Conference on Recent Developments in the Use of the MMPI* in 1966. This MMPI symposium was held annually, leading to a proliferation of research on the MMPI that had opened new research directions for the instrument.

Butcher and his colleagues also identified an even greater need for practical training in use of the instrument. They began to develop training workshops to present up-to-date research and clinical interpretive strategies to practitioners. These workshops developed substantially and soon extended from domestic to international. Butcher himself traveled throughout the United States to give these workshops in order to make the programs accessible to professional psychologists. At one time, it was estimated that between 1,000 and 1,500 psychologists enrolled in these programs annually. Internationally, Butcher has traveled to 33 countries to give these workshops, leading to the extensive international application of MMPI/MMPI-2/MMPI-A. Currently, the MMPI-2 has 34 translations and the original MMPI has over 150 translations. MMPI/MMPI-2/MMPI-A has been among the most widely employed and internationally adapted personality inventories in clinical assessment.

An important topic of the annual MMPI symposium was whether the MMPI should be revised. Butcher and his colleagues soon concurred on such a need. Butcher was active in advocating and providing suggestions for the revision. The MMPI Revision Committee was formed in the early 1980s and Butcher and other two committee members were appointed to lead the revision team. They decided that the revision should retain the essential ingredients and strengths of the original MMPI yet allow for modernizing and removing some of the ineffective aspects that hampered its application. Led by Butcher, the revision task involved considerable consultation with experts and extensive data collection from both normative and clinical samples, which, after 10 years, culminated in the publication of the MMPI-2 in 1989 and the MMPI-A in 1992.

Butcher has effectively utilized his expertise and experience with MMPI/MMPI-2/MMPI-A in personality assessment at a more general level. Through his books and articles, he has called attention to the importance of revising outdated personality instruments and updating normative and clinical samples, and provided important principles, strategies, and recommendations for test revision procedures. His work led to him being awarded the Bruno Klopfer Award for Lifetime Contribution from the Society for Personality Assessment in 2004.

Similarly, with his expertise and experience from international application of MMPI/MMPI-2/MMPI-A, Butcher has provided an important framework for cross-cultural adaptation and validation of a personality instrument originally developed in a Western culture. In many of his books and articles, he discussed cultural factors, translation methods, and procedures to evaluate translation equivalence. In 1970, he founded the International Conference on Personality Assessment, through which international scholars discussed

their research and exchanged views on issues and techniques in personality assessment for intercultural contexts. His contribution to international personality assessment won him the Doctor Honoris Causa award from the Free University of Brussels, Belgium in 1990, and the Laurea ad Honorem in Psychology award from the University of Florence, Italy, in 2005.

Computer based application of personality assessment has been another important component in his scholarly works. Butcher had this interest in the 1960s but it became dormant during the years when he was heavily involved in the MMPI symposium, training, and revision. This interest was revived in the early 1980s when he was encouraged by his colleagues to develop a computer program for interpretation of the MMPI. Butcher then received funds from the University of Minnesota Press and National Computer Systems to develop this program, named the Minnesota Report. It was later published and adapted for use with adolescents, in personnel and forensic settings, and in cross-cultural contexts. During these years, Butcher had written many articles to discuss the use of computers in personality assessment, its reliability and validity, and challenges, and to provide guidance and directions for computerized clinical assessment.

Throughout his career in psychology, teaching has been an essential part of his professional life. Butcher has been actively involved in teaching and advising. In line with his research, his teaching covered a wide range of topics in personality assessment including various techniques, MMPI/MMPI-2, and cross-cultural study of personality. In addition, abnormal psychology was an important subject in his teaching. He has coauthored 11 editions of *Abnormal Psychology and Modern Life*, a widely used textbook for abnormal psychology and currently in its 16th edition. As the major advisor, he advised more than 50 doctoral dissertations between 1968 and 2003. Many of his students are now productive researchers and active practitioners in their own fields. Indeed, his own research program was both stimulated and broadened substantially by the contributions of many of his graduate students.

Butcher's professional life also included editorial services to many professional journals, and consulting services to both the profession of psychology and the community. Butcher is a fellow and member, and past member of the Board of Trustees of the Society for Personality Assessment. He was also a fellow and member of the APA during 1963–2009 for Division 12 (Clinical Psychology), Division 5 (Evaluation and Measurement), and Division 26 (History of Psychology). Butcher is the former editor of *Psychological Assessment*, an APA publication. He is one of the consulting editors and associate editors for the eight-volume set *Encyclopedia of Psychology*, published jointly by APA and Oxford University Press. He co-edited the 10-volume *Personality Assessment Series*, published between 1982 and 1995. He served on the editorial board fo*r* the *Oxford Handbook of Psychology* and currently serves as consulting editor for several other journals.

Butcher's interest in war planes since childhood developed into a professional interest in aviation psychology, leading him to provide professional consultation to airline pilot selection and airline disaster response management. Butcher has been involved in many forensic testimonies as an expert in many legal cases in which evaluations based on MMPI were involved. He provided his expert opinion on the interpretation of MMPI scores, technical aspects of the test, and meaning of a particular configuration of an MMPI profile.

A Pathway from Paperboy to Korean War Soldier, to Psychologist, to Artist

For many people, their professional accomplishments are more likely to progress along a straightforward journey, with a resourceful and supportive environment beginning in their childhood. However, this is not the case for Butcher, whose journey wound through unusually difficult circumstances, turns and twists, and surprising discoveries.

Butcher was born in Bergoo, West Virginia in 1933. He lived a very difficult early life in this coal-mining town. He lost both of his parents when he was young and he and his siblings had to raise themselves independently. Butcher started to earn money to support his siblings by delivering newspapers at age 11 and did so for most of the remainder of his school years. Butcher enlisted in the U.S. Army at age 17 after graduating from high school, beginning his search for an identity. He served in the military for three years and was deployed to Korea where he fought two major battles in the final years of the war (1952–1953). His combat experiences and the living conditions on the front are graphically described in his book, *Korea: Traces of a Forgotten War*. While going into the military might seem to be a false start in his professional journey to psychology, his experience and interactions with a South Korean soldier and people from other cultures may have planted a seed for his interest and involvement in cross-cultural personality research 20 years later.

Butcher's journey from being a paperboy to a Korean War serviceman did not immediately turn to psychology after his discharge from military service. Readjusting to civilian life, he tried jobs such as sales and private detective, but soon found them not the right choices. The critical turning point to psychology occurred when he was evaluated through a psychological test on mathematics and reasoning for an insurance job. Butcher was rejected, however, not because he was not qualified given the test results, but rather he was overqualified for such a position. Instead of hiring him for the position, the job interviewer expressed his great confidence in Butcher's potentiality and encouraged him to go to college to further explore and actualize such potentiality. His confidence and encouragement led Butcher to a BA degree in psychology from Guilford College in North Carolina in 1960 and his continued pursuit of an MA in experimental psychology from the University of North Carolina in 1962.

However, although pursuing a career in psychology, Butcher's professional pathway had not been aligned to clinical psychology and personality assessment until he took a clinical course. As part of the requirement of the course, Butcher began his practicum at a local hospital that involved intensive clinical assessment. This clinical experience made his professional pathway to clinical research and assessment solid and crystal, leading to his PhD in clinical psychology from University of North Carolina in 1964. In the same year he published his first professional article on effect of social economic status on MMPI differences between Black and White Americans, an event that imprinted him on MMPI research.

Butcher's professional pathway in psychology followed an academic direction when he became a faculty member in the Department of Psychology at the University of Minnesota in 1964. This is a place where he found a sense of belonging, began the MMPI symposium and training workshops, taught and advised, and made significant contributions to psychology. Yet, this pathway did not end there, but surprisingly took another turn as his

retirement was approaching. In transitioning toward retiring, he accidently uncovered his talent in watercolor painting, which had remained unrecognized and dormant in his previous personal and professional life. His *Bike Trail in Excelsior* is the cover of the October, 2005 issue of *American Psychologist*, and his *Vicksburg Courthouse* was the jacket cover of his book (with Pope and Seelen), *The Use of the MMPI/MMPI-2/MMPI-A in Court*, published by APA in 2006.

Charles S. Carver

Jessica Borelli[1] and Betsy Blackard[2]

[1] *University of California, Irvine*
[2] *Claremont Graduate University*

APS Fellow Charles S. Carver (1947–2019) was the Director and Professor of the Adult Division within the Department of Psychology at the University of Miami and a foundational researcher in the the field of personality psychology. He was the creator of several widely-used scales or measures in social psychology and the recipient of numerous awards.

Dr. Carver received his doctorate from the University of Texas at Austin in 1974 after earning an AB in psychology from Brown University in 1969. His interest in psychology was sparked at Brown, where what fascinated him most about his then-favorite subject, literature, were the characters in the stories, specifically their motivations and beliefs. Shortly after receiving his PhD in experimental personality psychology, he became an Assistant Professor of Psychology at the University of Miami, and ultimately a Distinguished Professor.

He served as an editor for four different publications, including six years for the *Journal of Personality and Social Psychology: Personality Processes and Individual Differences* and five years as an associate editor of *Psychological Review* from 2010 to 2015. He authored 10 books, including *Attention and Self-regulation: A Control-theory Approach to Human Behavior* and an undergraduate textbook on personality psychology entitled *Perspectives on Personality*, co-authored with Dr. Michael Scheier. He also wrote more than 400 articles and chapters and created 14 self-report measures, including some Spanish translations.

Dr. Carver's research spanned the disciplines of personality, social, and health psychology. Most of his research was related in some way to self-regulation processes, and included such diverse topics as the effects of stress and optimism on coping and resilience, impulse and constraint and how they are related to depression, behavioral approach and avoidance systems, and even adult attachment.

According to his website, Carver saw human beings as complex goal-directed systems that self-regulate their actions with respect to those goals. He examined the ramifications of effective and ineffective self-regulating strategies when having multiple goals at once, as well as when a person has difficulty reaching one of those goals. He was also interested in

approach and avoidance responses and how they are informed by self-regulation with respect to goals and "anti-goals." His book *On the Self-Regulation of Behavior*, co-authored with Dr. Scheier, is an overview of human functioning through this lens of behavior as goal-oriented and feedback-regulated.

Another area of Carver's research, much of which was conducted with Scheier, concerns optimism and pessimism and their role in coping and persistence in the face of adversity. With Scheier and others, Carver specifically studied coping as it pertains to health issues such as breast cancer and coronary disease. He was also interested in depression and the neurological origins it had in aggression and approach motivation, along with many other interests and projects. His research was funded by grants from the National Cancer Institute, the American Cancer Society, and the National Science Foundation.

Carver developed or contributed to the development of many self-report questionnaires which he shared freely with the research community. These include the widely-used COPE (& Brief COPE) Inventory, which is used to assess coping responses; the LOT-R (Life Orientation Test – Revised), which assesses individual differences in optimistic and pessimistic dispositions, and BIS/BAS scales, which measure the sensitivity of incentive and aversive motivational systems. He also developed numerous others, including the Revised Self-Consciousness scale, which assesses private and public self-consciousness, as well as several scales that measure self-esteem and quality of life for those diagnosed with breast cancer.

During his career, Carver earned eight awards, including four from the American Psychological Association:

- Distinguished Scientific Contributions to Psychology Award, American Psychological Association, 2018
- Distinguished Lifetime Career Award, International Society for Self and Identity, 2012
- Jack Block Award for Distinguished Contributions to Personality Psychology, Society for Personality and Social Psychology, Division 8 of the American Psychological Association, 2011
- Distinguished Faculty Scholar Award, University of Miami Faculty Senate, 2011
- Donald T. Campbell Award for Distinguished Contributions to Social Psychology, Society for Personality and Social Psychology, Division 8 of the American Psychological Association, 2007
- Career Achievement Award, Stress and Anxiety Research Society, 2001
- Provost's Award for Scholarly Activities, University of Miami, 1999–2000
- Award for Outstanding Scientific Contribution to Health Psychology (Senior Level), Division 38 (Health Psychology) of the American Psychological Association, 1998

Dr. Carver was the first person to receive awards in all three of the disciplines of social, health, and personality psychology.

In memory of Carver's beloved dog, Calvin, who was an honorary member of the University of Miami Psychology department, the department has instituted the S.T. Calvin Award. This honor is awarded to one graduate student every year for excellence in quantitative methods. Carver is survived by his wife and collaborator Dr. Youngmee Kim, and their two dogs, Jahnghan and Tntnhan, two new honorary department members.

The field of personality psychology is indebted to Carver. In addition to generating numerous oft-cited self-report scales, his research on self-regulation, including coping, optimism,

and resilience has helped guide the direction of the field over the past three and a half decades. For more information, readers can visit www.psy.miami.edu/faculty/ccarver/.

Lee J. Cronbach

M. Justin Miller and Tiffany Smith

University of Wisconsin–Stout

Background

Lee J. Cronbach, an educational psychologist and renowned psychometrician, was an extraordinary scholar that made many contributions to the disciplines of education, evaluation, psychology, research, and statistics. He was born on April 22, 1916 in Fresno, California, and he died of heart failure on October 1, 2001 in Palo Alto, California. As a small child, in 1921, Cronbach was given an IQ test, which produced a score of 200. Owing to his high IQ score, Cronbach was selected by Lewis Madison Terman to be a participant of Terman's renowned program known as the Genetic Studies of Genius, also known as the Terman's Study of the Gifted.

Cronbach's intellectual gifts led him to accumulate a wide variety of educational experiences. At the age of 14, he graduated from Fresno High School. By the time he was 18 years old, Cronbach graduated with two Bachelor of Arts in chemistry and mathematics from Fresno State University. After graduating with his Bachelor degrees, Cronbach pursued a teaching credential at University of California, Berkeley, which he earned in 1935. After earning his teaching credential, Cronbach earned a Master of Arts in Education in 1937, also from University of California, Berkeley. Finally, Cronbach earned a Doctor of Philosophy in Educational Psychology from University of Chicago in 1940. Throughout the rest of his career, Cronbach received a handful of honorary doctoral degrees. He earned honorary Doctor of Humane Letters, also known as Litterarum Humanarum Doctorate, from Yeshiva University in 1966, the University of Chicago in 1979, and the University of Illinois in 1982. In addition, he earned honorary Doctor of Philosophy degrees from University of Gothenburg in 1977 and the University Autónoma in 1985.

After completing his educational endeavors, Cronbach returned to academia to build a 40-year career as a professor. In 1940, he became an assistant professor of psychology at Washington State University, where he taught until 1946. During his tenure at Washington State University, Cronbach was on leave from 1944 to 1945 to serve as an associate military psychologist for the United States Navy in San Diego, California through the University of

California's Division of War Research. After his time at Washington State University, Cronbach obtained an assistant professor of educational psychology position at the University of Chicago, which he held from 1946 to 1948. After leaving the University of Chicago in 1948, Cronbach obtained an associate professor of educational psychology position at the University of Illinois, which he held from 1948 to 1964. During his time at the University of Illinois, Cronbach served as a scientific liaison officer for the Office of Naval Research. In 1964, Cronbach obtained his final professor positions at Stanford University. He was first a professor of education from 1964 to 1966, then he was a Vida Jacks professor of education from 1966 to 1980. After retiring from teaching in 1980, Cronbach held the status of professor emeritus at Stanford University until his death in 2001.

Major Research Contributions to Research and Statistics

Cronbach made major contributions to the field of research during his time in academia. In fact, Cronbach held the 48th position on a list of most cited psychologists in the twentieth century published by *A Review of General Psychology*. Cronbach's most notable contributions to the field of research relate to psychometric analysis, including internal consistency analysis through alpha reliability coefficients, as well as the construction of test-validity theory and generalizability theory.

To begin, Cronbach established coefficient alpha in 1951, now widely referred to as Cronbach's alpha. Cronbach's alpha is a revision of Kuder-Richardson Formula 20 that replaced the split-half reliability test as the most widely used reliability test of internal consistency. The purpose of coefficient alpha is to test the internal consistency of coefficients. More specifically, coefficient alpha is essentially the correlation between all possible split-halves of a measure. Thus, the importance of coefficient alpha derives from the non-unidimensional nature of the reliability test. Therefore, coefficient alpha allows multiple abilities, behaviors, and cognitions to be reliably measured simultaneously.

Following his work on coefficient alpha, Cronbach's next major contribution regarded the test-validity theory. Prior to Cronbach's work on validity, psychologists had been testing validity with simple correlational analyses. In 1955, in collaboration with Paul Meehl, Cronbach published "Construct Validity in Psychological Tests" in *Psychological Bulletin*. This publication helped bring clarity to the concept of validity. Further, this clarity helped to establish the four types of validity, which are still taught in psychometrics and other measurement courses today. These four types of validity are concurrent validity, construct validity, content validity, and predictive validity. Cronbach and Meehl's aforementioned article combined concurrent validity and predictive validity to form the concept of criterion validity, which is still used modern research.

After Cronbach's work in test-validity theory, his major contributions shifted toward generalizability theory. The main purpose of generalizability theory is to assess the reliability of statistical measures. There were two major articles that Cronbach published that helped shape the concept of generalizability theory. In collaboration with Rajaratnam Nageswari and Goldine Gleser, Cronbach published "Theory of Generalizability: A Liberation of Reliability Theory" in 1963 in *The British Journal of Statistical Psychology*. This article provided a basis for generalizability theory, which was expanded upon in 1965 with Gleser,

Cronbach, and Rajaratnam's publication, "Generalizability of Scores Influenced by Multiple Sources of Variance," in *Psychometrika*.

Major Contributions to Education and Evaluation

Although Cronbach made many contributions to research and statistics, he also made important contributions that intersected in the fields of education, evaluation, and psychology. Before discussing this interdisciplinary and multidisciplinary work, it is worth noting that Cronbach made specific contributions to education. In fact, Cronbach's research and argumentations on the impact of learning environments and instruction have remained heavily influential in classrooms today. These research projects and argumentations spanned from understanding how learning processes are impacted by various contexts to advocating for a more holistic educational agenda, as opposed to one solely based in science.

Cronbach's work in educational program evaluations bridged the fields of education and evaluation. His work was highly influential in changing the use of evaluations in education to focus on course improvement through learning outcomes, which was highlighted in his 1963 article "Course Improvement Through Evaluation" in the *Teachers College Record*. Prior to Cronbach's work in educational program evaluation, the information that was being collected in educational evaluations for course improvement was lackluster due to only focusing on students' test performance. This narrow focus resulted in only certain aspects of classrooms being impacted and modified. Cronbach advocated for full course evaluations to optimize the classroom experience for students in multiple aspects, such as pedagogy, learning environment, and classroom context. Cronbach's work on course improvement helped to create systematic evaluations that are used in most if not all, post-secondary educational institutions today.

Although his contributions to educational program evaluations were considerable, Cronbach's contributions to the field of evaluation spanned beyond course improvement. Cronbach also made considerable contributions to evaluation practice through his work in utilization of evaluations, which focused on enlightenment use and generalizability through his units, treatments, observations, and settings (UTOS) model. More specifically, with his UTOS model, Cronbach posited a way to generalize evaluation methodologies from one evaluation to similar ones. Furthermore, to ensure enlightenment use of evaluations, Cronbach posited with the UTOS model that primary intended users should be brought along throughout the evaluation process due to their influence on organizations' policies.

Other Notable Works

As mentioned, Cronbach had many publications throughout his career, some of which have been discussed previously. However, it is vital to represent his work in a respectable regard by acknowledging some of his other major works. In the fields of education and psychology these works included *Exploring the Wartime Moral of High School Youth* (1943), *Essentials of Psychological Testing* (1949), and *Educational Psychology* (1954). Cronbach's

notable works in the field of evaluation included *Toward Reform of Program Evaluation* (1980) and *Designing Evaluations of Educational and Social Programs* (1982). In addition, Cronbach was the editor for *Text Materials in Modern Education: A Comprehensive Theory* (1955) and *Platform for Research* and *Readings for Educational Psychology* (1964).

Acknowledgments and Awards

Cronbach was honored with leadership positions and memberships in a variety of academic associations for his many academic contributions. To begin, Cronbach was a member of the American Psychological Association (APA). From 1950 to 1953, Cronbach held a chair position on the Committee on Test Standards for the APA. In addition, he served on the APA's Publication Board from 1951 to 1953 and the APA Board from 1952 to 1958. In 1957, Cronbach was elected president of the APA, a position that he held for one year. In addition to his presidency in the APA, Cronbach was the president of other professional organizations during his lifetime, including the Psychometric Society and the American Educational Research Association. Cronbach was also the director of the Stanford Evaluation Consortium at Stanford University during the 1970s. Aside from his presidencies and directorship in these professional organizations, he also held memberships in the American Philosophical Society, the American Academy of Arts and Sciences, the National Academy of Education, and the National Academy of Sciences during his academic career.

Owing to Cronbach's major contributions and scholarship, he received many acknowledgments and awards. In 1965 he was elected into the National Academy of Education. For his many research contributions, the University of Tokyo awarded Cronbach a Fulbright fellowship from 1967 to 1968. In 1973, he received the Distinguished Scientific Contribution Award from the American Psychological Association for his work on coefficient alpha, test-validity theory, and generalizability theory. Similarly, for these major contributions, Cronbach was selected into the National Academy of Sciences in 1974. In 1979, Cronbach received the Alva and Gunnar Myrdal Science Award from the American Evaluation Association.

Conclusion: Personality and Individual Differences

In conclusion, Cronbach made many contributions to the fields of education, evaluation, psychology, research, and statistics, and he has received a vast amount of recognition for these contributions. It is notable that some of these contributions and recognitions were due to Cronbach's work in individual differences and personality research. For instance, Cronbach's work in education shed light on the influence of different learning environments, learning processes, and behaviors on student outcomes. Therefore, Cronbach created ways to better foster learning in classroom settings by taking individual and environmental differences into consideration.

Cronbach's work in research and statistics also heavily influenced personality measurement. In fact, Cronbach's alpha is a key component to constructing personality models based in reliable measures because alpha reveals the internal consistency of measures, as

well as sub-measures within the measure. In addition, multiple personality traits, or various aspects of a personality trait, can be measured simultaneously due to Cronbach's work in psychometrics. Owing to the nature of personality research, this contribution has greatly helped the progression of research in personality and individual differences through the ability to construct models based in various personality traits. Overall, Cronbach's contributions have helped psychometricians to be more efficient in their research, and these contributions have greatly benefited society through research grounded in sound measures that he helped to create a system for developing.

Turhan Canli

Turhan Canli

Stony Brook University

Turhan Canli, Professor of Psychology and Psychiatry at Stony Brook University, made seminal contributions to the neuroscience and neurogenetics of individual differences in emotion, personality, and social behavior. He was born in 1966 in Germany, raised in Turkey and Germany, and immigrated to the United States in 1985 after completing the German Gymnasium. He received his undergraduate BA in Psychology (s*umma cum laude*, *summo cum honore in thesi*) from Tufts University in 1988, and his PhD in Psychobiology from Yale University in 1993 in the laboratory of Professor Nelson Donegan. His postdoctoral education continued in behavioral neuroscience at Yale University (1993–1995) in the laboratory of Professor Thomas H. Brown, and in cognitive/affective neuroscience at Stanford University (1995–2001) in the laboratory of Professor John D. E. Gabrieli. During his California years, he also served as an instructor for one semester at the University of California, Berkeley, where he taught personality psychology while Professor Oliver John was on sabbatical leave. In 2001, he moved to Stony Brook University to join the faculty of the Department of Psychology, where he remains to date. At Stony Brook, he founded (and continues to direct) the Social, Cognitive, and Affective Neuroscience (*SCAN*) Center in 2008, and the Mind/Brain Center on War and Humanity in 2016, and served as Director of the Graduate Program in Genetics from 2010–2013. In 2017, he completed a Certificate in Refugee Mental Health from Harvard Medical School and expanded his work into the global mental health arena, and international humanitarian missions and human rights.

Early Contributions to the Neuroscience of Individual Differences in Emotion and Personality

Canli's early studies were in the domain of behavioral neuroscience and followed the Yale tradition of classical learning theory of the Rescorla-Wagner Model, focusing on the neural basis of learning and memory in Pavlovian learning phenomena and learned fear.

From there, Canli moved to Stanford to use functional magnetic resonance imaging to study emotional processes in the human brain. At a time when fMRI was a novel tool and most studies focused on highlighting consistent results across individuals, Canli instead focused on individual differences. During the Stanford years in Gabrieli's laboratory, Canli conducted the first imaging studies of individual differences in emotion, sex differences in emotional memory, and personality traits, which were published in *The Journal of Neuroscience* (Canli, Zhao, Brewer, Gabrieli, & Cahill, 2000), *Science* (Canli, Sivers, Whitfield, Gotlib, & Gabrieli, 2002), and *PNAS* (Canli, Desmond, Zhao, & Gabrieli, 2002), among others.

At Stony Brook, Canli expanded his investigations to include the role of genetic variants and gene-by-environment (G×E) interactions in the neural basis of individual differences in emotion and personality. This work was conducted in collaboration with Professor Klaus-Peter Lesch of Würzburg University, Germany, who was the first to publish on the role of allelic variation in the serotonin transporter gene in trait neuroticism (Lesch et al., 1996). The collaboration produced a number of imaging studies, which eventually led to the proposed "tonic model" of serotonin transporter gene function in the amygdala (Canli & Lesch, 2007; Canli et al., 2005), which hypothesized that presence of the short allele was associated with elevated resting activation of the amygdala even in the absence of phasic fear-eliciting stimuli. The collaboration also produced the first G×E fMRI study of the serotonin transporter gene polymorphism (Canli et al., 2006), showing that both stimulus responsiveness and resting activation in the amygdala varied as a function of two variables: life stress history and serotonin transporter genotype.

Molecular Psychology

Canli coined the term "molecular psychology" in an edited volume for Oxford University Press (Canli, 2015c) to delineate a research field using the tools of molecular biology/genetics/-omics applied to the study of behavior. According to Canli, "molecular psychology" began in 1996 with the discovery that specific gene variants map onto individual differences in complex personality traits (while acknowledging that molecular tools have long before been used in behavioral neuroscience), but later expanded to include a wider range of molecular processes such as gene regulatory mechanisms, epigenetics, -omics, optogenetics, and genetic engineering methods such as CRISPR. Canli's interest in mechanisms of gene expression regulation and genomics led to two lines of research: one which addressed epigenetic mechanisms of gene-by-environment interactions (Duman & Canli, 2015), and a second which for the first time identified genome-wide gene expression networks in the human brain associated with social cognition, such as loneliness (Canli et al., 2017). The latter discovery was of particular significance because it showed that a wide range of somatic illnesses known to be exacerbated by social isolation are connected via an underlying gene regulatory network, with implications for the study of social regulation of disease genes from cancer to heart disease to inflammatory illness.

Depression as an Infectious Disease

In 2014 and 2015, Canli published and presented his ideas on depression as an infectious disease to academic (Canli, 2014a, 2014c) and public audiences (Canli, 2014b). He hypothesized that, for a subset of patients, changes in specific brain regions associated with depression are caused by either known or yet-to-be-discovered pathogens that can rewire neural systems, as has already been discovered to be the case with *Toxoplasma gondii* and other parasites that are capable of changing an infected host's behavior. Canli's theory builds on an emerging consensus that depression is associated with activation of the immune system to systemic infection (Dantzer, O'Connor, Freund, Johnson, & Kelley, 2008), but goes further by proposing brain-specific mechanisms initiated by activation of disease-specific viral, bacterial, or parasitic pathogens. The proposal caught the attention of many practitioners and patients: the peer-reviewed publication had been accessed more than 82,000 times and the TEDx talk had been viewed by more than 182,000 by the end of 2019. In 2019, Canli published an updated theory on the role of human endogenous retroviruses (HERVs) in mental health, suggesting that trauma or viral infections can activate HERVs embedded in human DNA to promote resilience or vulnerability (Canli, 2019). Research in Canli's laboratory on this topic is ongoing.

Neuroethics

In 2006, Canli joined colleagues from neuroscience, ethics, law, and related disciplines in Asilomar, California, to form the "Neuroethics Society" (later renamed the "International Neuroethics Society," www.neuroethicssociety.org), which is concerned with the ethical, legal, and social implications of the use of neuroscience and its discoveries in the real world, such as cognitive enhancement, lie detection, brain-machine interfaces, vegetative and minimally conscious states, neuroprivacy, and neuromarketing. He served on the Society's Executive Board from 2006 until 2015, and organized its first two annual meetings. At Tufts University in 2006, he organized a conference and workshop on neuroscience applications in national security (Canli et al., 2007), whereas his later work in neuroethics focused on the role of genetics and genomics within the emerging field of what Canli called "neurogenethics" (Canli, 2015a, 2015b).

Global and Refugee Mental Health, Humanitarian Work, and the Founding of the Mind/Brain Center on War and Humanity

Since 2016, Canli has become increasingly involved in global mental health and human rights issues. While earning a Certificate in Refugee Mental Health from Harvard Medical School, Canli developed an international network of frontline mental health professionals, scientists and scholars, clinicians, healers, educators, policy-professionals, and non-governmental activists whom he recruited to the Mind/Brain Center on War and Humanity (www.stonybrook.edu/commcms/mindbraincenter/index.php), which focuses on the "human

condition in times of war." It seeks to identify communal, social, psychological, genetic, and neural factors and mechanisms that contribute to individual differences in thoughts and actions in times of war, such as political cognition, threat perception, biased thinking, and dehumanization, as well as forgiveness and compassion. Of particular interest are individual differences in mental health vulnerability and resilience following war trauma among military veterans, refugees, and former child soldiers, and the interplay between community and the individual to either exacerbate political conflict or promote individual and communal healing, reconciliation, and (re-) integration. Canli spoke about the mission of the Center at the UN University in Maastricht, the Netherlands; Toronto, Canada; and the University of Kisubi, Entebbe, Uganda. As of the end of 2017, the Center was engaged in humanitarian, clinical, or research projects in Syria, Turkey, and Uganda.

Philip J. Corr

Philip J. Corr

City, University of London

Philip J. Corr, Professor of Psychology at City, University of London, has plowed a number of scientific furrows since receiving his doctorate in 1994 from the Institute of Psychiatry (IoP; now the Institute of Psychiatry, Psychology and Neuroscience, at King's College London, UK), where he researched the biological bases of personality, contrasting Jeffrey Gray's and the world-famous Hans Eysenck's theories – at the time Philip could not have imagined that he would, some 20 years later, publish a biography of this most remarkable of psychologists (Corr, 2016). Since his doctoral days, Philip has sought to make incremental progress in the general area of personality and individual differences. He has single and co-authored well over 150 papers, many book chapters, and is the co-author and editor of a number of other books. Philip relishes the opportunity to work and publish with colleagues around the globe, especially younger ones in the early steps of their career – he remembers well the support and guidance that was of such importance in his own academic development from, amongst others, such luminaries as Jeffrey Gray and Hans Eysenck. Philip held previous professorial appointments at University of East Anglia and Swansea University, both in the UK.

Philip has won several awards, starting with the Early Career Development Award (2001), from the International Society for the Study of Individual Differences (ISSID), where later he was honored by being elected by society members to the board of directors, and then president-elect (2013–2015) and president (2015–2017). In the UK, Philip co-founded the British Society for the Psychology of Individual Differences (BSPID), in which he was co-president for its first 10 years. Philip's research interests are in the general area of personality neuroscience, including its extension to, amongst other things, behavioral economics. Specifically, his personality neuroscience research concerns individual differences in fundamental systems of emotion and motivation that underlie approach and avoidance behavior, and their conflict. He believes that such fundamental systems hold wide-spread importance across the whole landscape of psychological phenomena.

Philip has worked extensively with the Reinforcement Sensitivity Theory (RST) of personality, and in 2008 he edited a book by this title. He has worked alongside Professor Neil McNaughton (Otago University, Dunedin, NZ) on developing this neuropsychological approach to personality (e.g. Corr & McNaughton, 2012), first formulated by Professor Jeffrey Gray in the early 1970s. This theory proposes that at the basis of personality – and its links to internalizing and externalizing mental disorders – are three systems: one positive, the Behavioral Approach System (BAS); and two negative, the Fight-Flight-Freeze System (FFFS) and the Behavioral Inhibition System (BIS). The BAS is activated by appetitive (attractor) stimuli; the FFFS by aversive (repulsor) stimuli; and the BIS by conflicting stimuli (e.g. co-activation of FFFS and BAS). This general theoretical framework has increasingly been seen as offering an integrative model for the neurobiology of personality and, also, psychopathology. A theoretically faithful questionnaire of revised RST has been developed by Philip and Andrew Cooper (Goldsmiths, University of London, UK; Corr & Cooper, 2016), which was some 10 years in the making and, if nothing else, attests to the doggedness of Philip's research strategy and, where appropriate, the desire not just to publish to get a quick academic "fix."

Philip has applied his neuroscience-informed individual differences approach to many specific areas of psychology, including psychopathology (Corr & McNaughton, 2015); consciousness (Corr & Morsella, 2015); perfectionism (Stoeber & Corr, 2015); laterality (Beaton, Kaack, & Corr, 2015); social attitudes (Corr, Hargreaves-Heap, Russell, Tsutsui, & Seger, 2013); gambling (Corr & Thompson, 2014); psychopharmacology (Perkins, Ettinger, Weaver, Schmechtig, Schrantee, Morrison, Sapara, Kumari, Williams, & Corr, 2013); psychophysiology (Andersen, Moore, Venables, & Corr, 2009); health psychology (Kalogreades & Corr, 2011); creativity (Burch, Pavlis, Hemsley, & Corr, 2006); occupational performance (Corr, McNaughton, Wilson, Burch, & Poropat, 2017); and neuroimaging and genetics (Ettinger, Corr, Mofidi, Williams, & Kumari, 2013). A major recent theme has been to work toward integrating personality and (especially behavioral) economics (Ferguson, Heckman, & Corr, 2011).

Much of Philip's work combines an experimental approach with individual differences in personality and cognitive variables. This follows the course of trying to combine these two major schools of psychology, as outlined by Cronbach's, 1957, American Psychological Association Presidential Address. This scientific perspective contends that a truly unified psychological science needs properly to consider both sides of this perspectival scientific coin. To achieve this end, there needs to be a revival of the generalist in psychology, which Philip's research typifies.

John M. (Jack) Digman

Lewis R. Goldberg and Sarah E. Hampson

Oregon Research Institute, Eugene, Oregon

Jack Digman spent most of his boyhood in Cincinnati, Ohio; he attended Ohio State University, where he obtained his BA in 1948 and his PhD in 1951, both in experimental psychology. From 1951 to 1991, he taught in the Psychology Department at the University of Hawaii, where he served as president of its faculty senate in 1966–1967. He was an early member of the Society of Multivariate Experimental Psychology, and served as its president in 1978–1979. Upon his retirement from the faculty in Hawaii, he became a research scientist at the Oregon Research Institute in Eugene, Oregon, where he worked with the two authors of this biography.

Digman was hugely influential in popularizing the five-factor model of personality structure, in part through his own seminal work on teachers' ratings of child temperament, in part through his creative re-analyses and syntheses of other studies of personality structure, and in part because of his influential essays on the history of the five-factor model. Digman left another invaluable legacy in the form of the teachers' ratings of child personality traits which became available for use by others, and which were used to form the childhood database for the ongoing Hawaii Personality and Health Longitudinal Study.

From 1959 to 1967, Jack persuaded 88 elementary school teachers on the Hawaiian islands of Oahu and Kauai to rank-order each of their students on around 50 personality traits at the very end of the school year. The resulting detailed descriptions of over 2,400 children forms one of the most comprehensive collections of children's personality traits ever obtained. For information about the exact methods and the specific traits used in each of his six samples, see Goldberg (2001).

In preliminary analyses of portions of this rich data-set (Digman & Takemoto-Chock, 1981; Digman & Inouye, 1986), Jack became convinced of the usefulness of the five broad personality factors (Digman, 1989) that would later be labeled by Goldberg (1990) as the Big Five factor structure. Digman's findings from these preliminary analyses, plus the findings from analyses of other data sets by Goldberg, led Costa and McCrae to expand their initial three-factor NEO inventory to include the five-factor structure included in the

NEO-PI-R. With a Russian colleague, Digman explored the structure of temperament and personality in Russian children (Digman & Shmelyov, 1996). In one of Jack's final publications (Digman, 1997), he espoused a higher-level two-factor structure that has become a useful addition to the five-factor models. In addition, his historical accounts of the development of the Big Five model (Digman, 1990, 1996) have been widely cited.

Over the years, Jack's colleagues encouraged him to conduct a follow-up of the participants in his studies of childhood personality traits, so as to be able to study the stability of the Big Five personality traits from childhood to adulthood and their relation to life outcomes. By the mid-1990s, there was an additional motivation. Howard Friedman and his colleagues had recently published their remarkable findings from the Terman Life-Cycle study, showing that conscientiousness at age 11 predicted longevity (Friedman, Schwartz, Tomlinson-Keasey, Tucker, Martin, Wingard, & Criqui, 1995). A follow-up of Digman's childhood samples would enable the study of the processes by which childhood personality traits influenced health and mortality. Together, these arguments proved persuasive, and in 1998 he was awarded a research grant from the National Institute of Mental Health to find the members of the original childhood samples, by then in their 40s, and recruit them for new studies. Tragically, Jack Digman died shortly after receiving this award.

Despite this setback, others took up the program of research he envisioned. This study, now known as the Hawaii Longitudinal Study of Personality and Health, has continued for the past 20 years and is ongoing. When Digman collected the childhood personality data, he had no plans to maintain contact with the children over the long-term. Consequently, the effort to find the members of his childhood samples, now adults, was limited to first and last names and their elementary schools as a starting point. Nevertheless, over 80% of the original children have now been located and over 70% of those agreed to take part in follow-up studies (Hampson, Dubanoski, Hamada, Marsella, Matsukawa, Suarez, & Goldberg, 2001). The participants are representative of the ethnic and cultural diversity of classrooms back in the 1960s, providing a rare opportunity to study minorities such as Native Hawaiians, Part-native Hawaiians, and Japanese Americans. Follow-up research, using questionnaires and in-person medical and psychological assessments, has yielded a number of contributions to topics in personality psychology, two of which are highlighted here: personality stability and personality and health.

Personality stability is a basic assumption of trait theory. Yet, the degree of stability of personality over the lifespan, and particularly over important development periods, such as from childhood to adulthood, has been controversial. The Hawaii study, with comprehensive Big Five measurement in childhood and Big Five factors assessed 40 or more years later using self and observer reports, is well-placed to examine personality stability across the lifespan. Contrary to previous conclusions, the Hawaii study demonstrated that the Big Five traits are not all similarly stable (Hampson & Goldberg, 2006; Edmonds, Goldberg, Hampson, & Barckley, 2013). Whereas extraversion and conscientiousness exhibited substantial stability, emotional stability exhibited virtually no stability at all.

Among longitudinal studies of personality and health, the detailed childhood personality assessments obtained by Digman, and the length of follow-up of living participants, are unparalleled. With these data, the Hawaii study has advanced knowledge on

a number of fronts. The association between childhood conscientiousness and longevity demonstrated in the Terman Life-Cycle study suggested that a corresponding association with middle-aged health would be observed; more conscientious individuals should be in better health than those who are less conscientious. The Hawaii study supported this hypothesis, using both self-reported health and objective clinical biomarkers obtained at a medical examination (Hampson, Edmonds, Goldberg, Dubanoski, & Hillier, 2013). None of the other childhood Big Five factors predicted subsequent health status. Participants provided repeated assessments of their health-enhancing and health-damaging behaviors such as physical activity, dietary choices, and smoking. Their health-damaging behaviors mediated the association between childhood conscientiousness and middle-aged health status, along with educational attainment and cognitive ability (Hampson, Edmonds, Goldberg, Dubanoski, & Hillier, 2015). This finding added to existing support for a health-behavior model to explain associations between personality and health, and demonstrated apparently far-reaching effects of childhood personality on these behaviors over the lifespan.

A challenge for any longitudinal study is to anticipate which measures will prove useful in the future. The Hawaii study continues to benefit from Digman's perspicacity in appreciating the importance of a comprehensive childhood personality assessment. The study also benefits from the collection of a wide range of self-report and biological data, without necessarily knowing where such data may lead. A telling case in point was the decision early on to obtain dried blood spots for future genetic analyses. DNA was extracted from these samples and assayed for leukocyte telomere length, a marker of cellular aging. Less conscientious children were more likely to have higher body mass and to smoke, and these mediators were associated with shorter telomere length, indicating greater cellular aging (Edmonds, Hampson, Côté, Hill, & Klest, 2016). Without the comprehensive childhood personality assessments obtained by Digman, these far-reaching influences of childhood personality would not have been discovered. In the future, this study will provide insights into cognitive and physical resilience as participants enter their seventh and eighth decades.

Jack Digman died on May 25, 1998 of a cerebral hemorrhage; he was anticipating his 75th birthday on June 14th. As a scientist, Jack was most interested in the personality dimension labeled Conscientiousness, but as a human being he personified the factor of Agreeableness. We know of no one in the world who was so universally viewed as considerate, warm, kind, gentle, good-natured, peace-loving, helpful, conciliatory, good-hearted, modest, patient, tolerant, sympathetic, co-operative loyal, and agreeable. In a world that includes snakes and vultures, Jack Digman was one of the rare panda bears.

John E. Exner, Jr.

Cristina L. Magalhães

Alliant International University, Los Angeles

Few psychologists are known for a lifetime worth of achievements in both research and clinical training. John E. Exner, Jr. (1928–2006) was one of those exceptional individuals. His work amounts to an impressive collection of writings and countless conference presentations about his innovative ideas and groundbreaking research on the Rorschach Inkblot Test. He also made noteworthy contributions to the training of clinical psychologists around the globe and, independent of his written work, left an undeniable mark in the field through his extensive teaching and mentoring of clinicians in beginning and advanced stages of training. Exner embodied the professional values and identity of a true scholar-practitioner. He was a fine clinician, with exceptional assessment skills, dedicated to the pursuit of scientific discoveries with direct and relevant applications to clinical practice. This biographical entry describes highlights of Exner's life history, career trajectory, and contributions to the field of personality assessment through his brilliant and tenacious work with the Rorschach Inkblot Test. He is credited with having developed a comprehensive system for interpreting the Rorschach that integrates the best features of previous interpretative systems. His efforts revitalized interest in the test, and raised the standards for contemporary research and clinical practice with projective assessment measures.

John E. Exner, Jr. was born in 1928, in Syracuse, New York. He began his studies in psychology at Trinity University, a private liberal arts institution in Santo Antonio, Texas. His bachelor of science and master of science degrees were completed at Trinity, and he subsequently went on to pursue a doctorate at Cornell University in Ithaca, New York. He earned his PhD in clinical psychology from Cornell in 1958. Exner's early years as a clinical psychologist were spent as faculty at De Pauw University in Greencastle, Indiana; and as department chair at Bowling Green State University in Ohio. In 1968, he took a year's leave of absence from Bowling Green to direct the Peace Corps Office of Selection for the Africa, Near East, and South Asia regions; and in 1969, he joined the faculty at Long Island University (LIU). Exner was director of Clinical Training at LIU from 1969 to 1979, and is credited with being one of the founders of the LIU's doctoral program in clinical psychology. He retired from LIU in 1984 as professor emeritus, and dedicated his remaining years to the

Rorschach Workshops, a foundation he established to continue his research and training activities on the Rorschach Comprehensive System. Exner died in 2006, at the age of 77.

Exner's fascination with the Rorschach Inkblot Test begun in 1953, when he first laid hands on the test, and continued vibrant for the next five decades of his life. His earliest publication came out of his doctoral dissertation, in 1959. The article reported the results of an experiment he conducted while in graduate school in which color-modified cards were used to determine the influence of chromatic and achromatic color in test responses. The influence of color remained the focus of Exner's early publications but as he continued his research, efforts to understand, describe, critique, and integrate existing systems of interpretation of the Rorschach became central to his work. In 1969, Exner published *The Rorschach Systems*, a book describing five leading interpretative approaches developed by early Rorschach systematizers (Beck, Klopfer, Hertz, Piotrowski, and Rappaport-Schafer). It was not until 1974, however, that he introduced his own interpretative approach with the publication of *The Rorschach: A Comprehensive System*. His method capitalized on the strengths of previous systems and helped invigorate a field that had been struggling with keeping projective tests relevant in clinical practice.

Exner's publications date from 1959 to 2007. He wrote 14 books and dozens of journal articles about the Rorschach Inkblot Test during his entire career. His last publication, released posthumously in 2007, reported Rorschach data collected with a large non-clinical sample of individuals living across the United States between 1999 and 2005. Exner received many honors throughout his long and fruitful career, including the prestigious Bruno Klopfer Award in 1980, the Walter G. Klopfer Award in 1989, and the American Psychological Association Award for Distinguished Professional Contribution in Applied Research in 1998. He was active in national and international professional associations, and known as a leader in his field. He served as president of the Society for Personality Assessment (SPA) from 1974 to 1975, member of the Board of Trustees of SPA from 1987 to 1989, and was also president of the International Society of the Rorschach and Other Projective Methods, among other distinguished appointments. In 2010, as a testament to his commitment to mentoring students and young scholars, the SPA established a new award in Exner's name, to recognize and support the research of future generations of personality assessment investigators.

Oliver P. John

James Kean

Swinburne University of Technology

Background

Oliver Peter John was born on February 9, 1959. At the age of 18, John undertook a Bachelor's degree with a double major in economics and psychology at the University of Bielefeld in Germany in 1977. Following the successful completion of his undergraduate studies, John's passion for the field of psychology drove him to obtain a 12-month Fulbright Exchange scholarship to the University of Oregon in the USA in 1980. John returned to the University of Bielefeld to complete a Diploma of Psychology, but did not stay in Germany long before returning to the University of Oregon to begin his Doctor of Philosophy degree in social and personality psychology in 1983. Even before John had completed his PhD, he began to publish prolifically in the area of personality and the measures used to assess it. Further to this, John began to investigate the differences in the descriptive terms psychologists were using to describe personality in an article titled "Better than the alphabet: Taxonomies of personality-descriptive terms in English, Dutch, and German" (1984). In 1984, John was awarded the Bowerman Foundation Scholarship, which was presented to deserving recipients residing in Eugene, Oregon, which coincided with the William Stout award from 1984 to 1985. In 1986, John was offered a visiting assistant research psychologist position at the University of California Berkeley. Following this, John became an assistant and associate research psychologist within the Institute of Personality and Social Research at UC Berkeley as well as being awarded the position of assistant and associate professor within the Department of Psychology, a position he held for 10 years. John remained linked to his previous university, taking a position as an adjunct research scientist within the Oregon Research Institute between 1987 and 1992. Following this, John's work was noted as one of the top 25 most cited authors between 1990 and 1994. Furthermore, his consistent work ethic saw him obtain membership to the Society of Multivariate Experimental Psychology as well as the Personological Society and he was an invited scholar to the University of Michigan in 1994 and awarded as a Kurt-Lewin Fellow within the

University of Groningen in the Netherlands also in 1994. In 1995, at the conclusion of his associate professor role, Oliver P. John was made the acting director for the Institute of Personality and Social Research, University of California, Berkeley, until 1997. In 1999, John was awarded the position of professor at and has maintained his role at UC Berkeley until today.

Major Contribution: The Big Model of Personality Traits

In 1991, Oliver P. John, E. M. Donahue, and R. L. Kentle created version 4a and 4b of the Big Five Inventory – a self-report inventory designed to measure the five dimensions of personality as derived from previous work in the field by Cattell (1943), Comrey (1970), Wiggins (1979), Jackson (1984), Gough (1987), Myers and McCauley (1985), Hogan (1986), Tellegen (1982), Tellegen et al. (2003), Saucier and Ostendorf (1999), and Costa and McCrae (1992).

The Big Five Inventory has since become one of the most widely used assessments of personality in the world. Its structure is purposefully easy to understand so as to avoid bias toward any particular personality design structure. It is atheoretical, in that it allows the description of traits to be perceived in a non-dimensional manner providing a broader outlook upon each personality dimension.

The Big Five Inventory (BFI) is now a brief, multidimensional personality inventory consisting of 44 items in total composed of short simple phrases making it more accessible to the broader population. It is also available in 10 different languages and outcome data can be compared to sample means and standard deviations as described by John and Srivastava (1999, 2003). The BFI also comes in a shorter 11-item version, however, the complete version requires only five minutes to complete and remains the recommended inventory to use.

Other Notable Works: Emotion Regulation and Expressive Behavior

Oliver P. John has also worked in the field of emotional regulation and differences in individuals. His work, with psychologist James J. Gross, demonstrated the importance of individual differences in emotion and expressive behavior and the way these domains determine how an individual functions in social contexts (Gross & John, 1998). Through this work, John and Gross developed a measure denoted the Emotion Regulation Questionnaire (ERQ) that determines the level to which an individual will *express* positive or negative emotions and the relationship that outcome has to their *experience* of positive and negative emotions. They denoted the two categories of people as *reappraisers* and *suppressors*. Those who were characterized as reappraisers experience and express greater positive emotion and less negative emotion, whereas suppressors

experience and express less positive emotion but experience greater negative emotion. These findings indicated that as a person matures, the more they utilize reappraisal strategies, the better their emotional regulation became. This research was further extrapolated into the social context of living relationships investigating what is called *emotional convergence*. People with similar emotionality would be more likely to converge and have a mutual understanding and social cohesion and therefore, would be more likely to remain in that cohesive partnership, with a lower likelihood of their partnership dissolving.

This work highlights the impact of emotional mechanisms individuals tend to employ at a younger age and whether those mechanisms are more or less likely to strengthen an individual's ability to regulate their emotions as an adult.

Acknowledgments and Awards

Oliver P. John, PhD, is professor of psychology and research psychologist at the University of California, Berkeley, where he is also acting director of the Institute of Personality and Social Research. Dr. John has won the Distinguished Teaching Award from Berkeley's College of Letters and Science, the Theoretical Innovation Prize from the Society for Personality and Social Psychology, the Best Paper of the Year Award from the *Journal of Research in Personality*, and the Cattell Award for Early Career Contributions from the Society of Multivariate Experimental Psychology. In more than 90 articles and three books, Professor John has examined personality structure, emotion regulation, and self-perception, as well as their measurement and the methodological issues with that measurement.

Conclusion: Personality and Individual Differences

Professor Oliver P. John contniues his work at UC Berkeley as the director of the Berkeley Personality Laboratory. He continues to publish on the Big Five Inventory (BFI-2) with recent publications on the German adaptation of the inventory. He continues to work on the taxonomy of psychotherapy in various contexts including alcohol use disorders, with a specific focus on emotion regulation skills and reinforcing them through therapy. He is currently the co-principal investigator of the Mills Longitudinal Study, a 50-year long investigation of adult development that has been following a cohort of women since their graduation from Mills College in the 1950s. There are approximately 100 participants still in the study that started with 140, with 123 followed up. John examines the developments in the participants' personality, emotional experience, as well as emotional expression and regulation. To date, John continues to update his work on the Big Five Inventory. His work continues to be some of the most influential in the field of personality and individual differences around the world.

Henry A. Murray

Cory L. Cobb[1], Dong Xie[1], and Alexandros Maragakis[2]

[1]*University of Central Arkansas*
[2]*Eastern Michigan University*

Henry Alexander Murray (1893–1988) was an American psychologist who taught at Harvard University for over 30 years. Murray served as the director of the Harvard Psychological Clinic beginning in the 1930s and was the founder of the Boston Psychoanalytic Society and Institute. Murray's work at Harvard played a substantial role in reshaping the landscape of American psychology. In particular, Murray was instrumental in expanding the horizon of academic psychology to include areas of research yet to be explored such as personality, abnormal, and clinical psychology. As such, Murray was a pioneer in the field of psychology and his work continues to be the foundation of much research today.

Although Murray made many contributions to the field of psychology, his greatest contribution was in personality theory. The publication of *Explorations in Personality: A Clinical and Experimental Study of Fifty Men of College Age* in 1938 marked the beginning of Murray's identity as one of America's leading personality theorists. The publication of this book was Murray's crowning accomplishment as an early career psychologist and set the foundation for his future research on personality. Another major achievement made by Murray was his development of the Thematic Apperception Test (TAT), which continues to be one of the most widely used and researched projective personality tests.

Before Murray's debut into the field, systematic research on personality was scarce. Topics such as abnormal psychology and psychotherapy were regarded to be outside the realm of American academic psychology. Murray served as a channel through which European personality and clinical theories would become an integral part of American academic psychology. Murray's unique academic training in medicine, biochemistry, and Freudian and Jungian psychology permitted him to approach personality psychology from an interdisciplinary perspective, as well as provide a unified structure of psychoanalysis that could be investigated holistically.

Childhood and Early Education

Murray was born on May 13, 1883 in New York City to a wealthy, conservative family and was the second of three children. Receiving an inheritance from his grandfather, Murray lived a life of ease while growing up on the Eastern seaboard. Murray spent many of his summers on Long Island beach and made four long trips traveling to Europe with his parents. Most of Murray's early recollections center on his privileged background. Only a few of his early childhood experiences would impact his later career decision.

One event that helped to shape Murray's future career choice was his exposure to family members with psychiatric illnesses of varying degrees and severity. Murray had two aunts that suffered from psychological illnesses and a mother who was overly prone to migraine headaches. Murray's relationship with his two aunts made him more sensitive to emotional problems and disturbances. Another event that impacted Murray's future career was his emotional detachment from his mother. Murray described his mother's emotional detachment and proneness toward his siblings as the source of his lifelong depression, a condition that would eventually form the center of his theory.

Murray later received an education at some of the most exclusive private schools on the Eastern seaboard. After attending Groton, a preparatory institution, Murray went on to attend Harvard in 1911 where he remained largely undistinguished as a history major. After graduating from Harvard in 1915, Murray attended medical school at Colombia University in New York where he found himself serious about his studies for the first time. During his first year of medical school, he married Josephine Rantoul and had one child, Josephine Murray, who became a pediatrician in Boston. During his time at Colombia, Murray completed a MA in biology and a MD degree, which was followed by a 20 month surgical internship at Presbyterian Hospital in New York. Murray went on to study biochemistry at Cambridge University where he completed a PhD in 1927.

Transition to Psychology and Psychoanalysis

In 1923, during his tenure at Cambridge, Murray read Carl Jung's *Psychological Types* which would serve as the catalyst for his interest in psychology. Murray's sudden fascination with Jungian psychology led him to read all of Jung's published writings and eventually write to Jung in the hope of a possible visit. In 1925, Murray met with Jung for three intense weeks in Zurich, Switzerland, where his psychological interest and adeptness increased. Also, Murray's interest in psychology and personality was further spurred on by his acquaintance with Christina Morgan, an artist who shared many interests with Murray including a fascination with Jung, the unconscious, and the writings of Herman Melville. This relationship continued throughout Murray's lifetime and was influential in Murray's transition to psychology.

During his three weeks with Jung, Murray analyzed much material that had been released due to his increasing awareness of the feminine-intuitive aspect of his personality. This feminine aspect of personality contrasted the masculine, logical, and scientific aspects that were usually emphasized in his medical and biochemical research. Murray eventually made the decision to leave the field of biochemistry and pursue a professional career in

psychology. However, Murray was not someone who would abandon prior commitments. Before he could make the transition to psychology, he first needed to finish his doctoral studies in biochemistry and would go on to publish three more articles on developmental embryology.

Given his time with Jung, coupled with the aforementioned factors that contributed to his interest in psychology, Murray viewed 1925 as his rebirth. He returned to America with the goal of combining his medical training with academic psychology. Murray's transitioning career interest was first seen in an article he wrote for *The Independent* in 1926. The article reviewed published manuscripts in psychology and focused almost exclusively on abnormal psychology. The article centered primarily on Freud's *Collected Papers* and Jung's *Psychological Types*, both of which regarded various aspects of abnormal psychology. Thus, Murray's new professional identity as an aspiring psychologist was being established. He eventually made the decision to become a psychotherapist and conduct research on psychopathology in clinical and hospital settings. In 1926, the President of Harvard, A. Lawrence Lowell, invited Murray to be an assistant to Dr. Morton Prince in the newly formed Harvard Psychological Clinic, where Murray spent many years conducting research and developing his theory of personality.

The Harvard Psychological Clinic

In the fall semester of 1926–1927, psychologist Morton Prince established the Harvard Psychological Clinic to study abnormal psychology and personality. Prince believed that abnormal psychology needed to be separated from the medical discipline of psychiatry. He felt that research needed to advance the study of psychopathology would take a backseat to practical concerns associated with medical school, such as running a hospital or psychiatric facility. Initially, Prince was the only faculty member in the clinic but with a recommendation from a colleague and the approval of faculty, Murray was hired as his research assistant. By the spring of 1928, Prince's health had declined which forced him into retirement. This meant that Prince would have to choose a successor. The clinic's endowment required that the director be an experienced physician and psychologist trained in laboratory methods. Because Murray met these criteria, along with two years as Prince's assistant, he was considered the most appropriate person for the job.

However, Murray's appointment as director of the clinic was not without controversy. Other faculty members questioned whether Murray was the best successor to Prince. Edwin G. Boring, who initially supported Murray's appointment as research assistant, led the opposition against his advancement to director. One reason for this controversy was that Murray's PhD was in biochemistry rather than psychology. Also, Murray's newly found fascination with Jungian and Freudian psychology caused others to doubt whether he would possess the scientific rigor needed to operate the clinic. Boring argued for someone else to be appointed director, namely, someone who would not only meet the clinic's endowment requirements but better fit his own experimental orientation. Nevertheless, the final decision was up to President Lowell who sided with Prince in appointing Murray as director. In the 1928–1929 academic year, Murray was appointed as assistant professor and director of the clinic.

At the Harvard Psychological Clinic, Murray believed that academic psychology was misguided at the time and made every effort to further learn about psychoanalysis. Murray helped to form the Boston Psychoanalytic Society in 1928, took a nine-month training appointment to study psychoanalysis under Alexander Franz in 1931–1932, practiced psychoanalysis under the supervision of Hanns Sachs, and became a member of the American Psychoanalytic Association in 1933. For Murray, psychoanalysis became the core framework that would drive his research and theory.

In the 1930s, Murray and Morgan developed the Thematic Apperception Test (TAT), a projective test that assessed individual personality and self-understanding. Although Murray is generally credited for the development of the TAT, it was actually Morgan who did most of the work. Despite Morgan's substantial contribution to the development of the TAT, her name was eventually dropped from the publication. This decision was agreed upon by Murray who was left as the sole author. The TAT became a best-seller for the Harvard University Press and continues to be one of the most widely used projective personality measures today.

In 1938, Murray established his identity as a leading personality theorist with the publication of *Explorations in Personality: A Clinical and Experimental Study of Fifty Men of College Age*. The book presented in detail Murray's dynamic conception of personality as the study of individuals' lives and emphasized his elaborate taxonomy of needs and characterization of persons and human transactions. The most important component to this work was Murray's reliance upon psychodynamic theories as the foundation for many of his concepts. Murray strongly contended that psychoanalysis was the only viable approach to the science of psychology that addressed totality and complexity of human behavior. Another central component to this work was the use of the Diagnostic Council of senior researchers to integrate multiple perspectives on each subject provided by the contributing researchers. Each researcher in the Diagnostic Council served as a medical specialist who critiqued the personality formulations by the other council members, as well as responded to critiques of others. Eventually, the goal was to converge on an analysis of personality that was accepted by all. Overall, this classic publication secured Murray's status as a leader in the systematic, holistic, and dynamic study of personality.

Theory of Personality

Murray's system of personality, known as *personology*, stemmed from his interdisciplinary background in biochemistry, medicine, and psychoanalysis. Murray's personology was developed on five core principles that served as a guiding framework for the rest of his theory. Although Murray's personology system is complex and consists of many elements, the five core principles remain at the center of the theory and its development.

The first principle of personology suggests that personality is ultimately rooted in the brain. As such, a person's cerebral physiology guides and determines every aspect of personality. Everything on which personality ultimately depends is found in the brain including: emotional states, memory, conscious/unconscious states, beliefs, attitudes, values, and fears. Thus, it is the brain that dictates what an individual's personality is, as well as what it might be should the brain be altered in any way.

A second component to Murray's system is the concept of tension reduction. Murray concurred with Freud and other theorists that people act to reduce physiological and psychological tension. However, people do not strive to achieve a tension-free state; rather, it is the process of acting to reduce tension that brings satisfaction, not attaining a state where all tension is absent. Murray contended that a tension-free state is actually a source of distress. According to his theory, people need excitement, movement, motivation, and activity in their lives. Each of these needs increase tension which people then act upon in an effort to reduce it. For Murray, the ideal state of human nature is to always have a certain level of tension to reduce.

A third core component of Murray's personology is the idea that personality continuously develops over time and is composed of all the events that happen over the course of a person's lifetime. Therefore, in order to understand personality, it is critical to consider the past and how it shapes the individual personality over time.

A fourth component of Murray's system is that personality is always changing and is never static or fixed. Therefore, an individual's personality at one point in time will almost certainly be different from personality at a later point in time. This notion of a constantly changing personality continues to be of interest to personality theorists today.

Fifth, Murray acknowledged the uniqueness of individual differences while also noting the similarities that all people share. Thus, Murray emphasized a tripartite component to individual personality: individual human beings are like no other people, like some other people, and like all other people. This model of individual personality recognized the importance of universal similarity, cultural specificity, and individual uniqueness.

Divisions of Personality

Along with the five core principles of personology, Murray divided personality into three components: the id, ego, and superego. Although Murray expressed these components in Freudian terms, they differed from Freud's traditional conceptualization in a variety of ways.

According to Murray, and similar to Freud, the id represented the source of all innate and impulsive tendencies. Thus, the id consisted of the lustful, unprincipled, and primitive impulses of human behavior. However, Murray differed from Freud in suggesting that the id also entailed innate impulses that society deemed desirable. For example, Murray contended that the id entailed tendencies to empathy, love, mastery of one's environment, and identification. As such, the influence of Jung can be seen in Murray's concept of the id. Jung's *shadow archetype*, which encompasses both positive and negative aspects, seemed to play an important role in Murray's conceptualization of the id. For Murray, the power of the id varies from person to person and manifests itself differently among individuals.

The superego represented an internalization of cultural values and norms. According to Murray, the superego is responsible for how individuals come to judge and evaluate their behavior and the behavior of others. The superego is mostly developed in early childhood by the imposition of the parents and other authority figures. However, unlike Freud, Murray believed that the superego was influenced by cultural factors and not limited to the child-parent interaction. Also, Murray deviated from Freud in his contention that the superego continued throughout one's lifetime and grew more complex as one got older.

Finally, Murray disagreed with Freud in that the superego was not in constant conflict with the id. Rather, because the id consisted of both positive and negative aspects, such positive aspects did not have to be suppressed.

The ego served as the logical and rational overseer of individual personality. When the id manifested negative impulses or tendencies, the ego's primary job was to delay or modify such impulses. Also, the ego was seen as the arbiter of the id and the superego, and could favor either one. For example, if the ego favored the id then behavior may be directed toward a life of negative behavior. On the other hand, if the ego favored the superego then behavior may be directed in a more positive or socially acceptable manner. For Murray, the ego can also combine these two aspects of personality so that what we desire (the id) is in agreement with what is deemed socially acceptable (the superego). Thus, Murray's concept of the ego was an extension of Freud's in that it served as the central organizer of behavior. He contended that the ego could reason, rationalize, and decide the ultimate direction of behavior.

Motivators of Behavior

One of Murray's most valuable contributions to personality theory was his notion of the use of needs to motivate and direct individual behavior. According to Murray, needs arise from physicochemical processes in the brain that organize and guide perceptual and intellectual abilities. Such needs can originate from internal processes such as hunger or thirst, as well as environmental stimuli. Because Murray believed that the ideal state was to reduce tension, he argued that needs bring about a level of tension which the person attempts to reduce by acting in a manner that will satisfy the needs. Thus, these needs motivate behavior and guide it in the appropriate direction that will eventually lead to the needs being satisfied.

Through his research, Murray formulated 20 needs. Each of these needs motivates behavior and varies according to individuals. Throughout one's lifetime, a person can experience all of these needs or only experience some of them. Murray divided his system of needs into four basic categories: primary needs, secondary needs, reactive needs, and proactive needs.

Primary needs (viscerogenic needs) stem from internal bodily states and entail survival needs such as hunger, thirst, sex, and air. Secondary needs (psychogenic needs) arise indirectly from primary needs and include states such as emotional satisfaction or achievement. For Murray, secondary needs are not necessarily less important than primary needs but are called secondary because they ultimately arise from the primary needs.

Reactive needs are concerned with responses that occur due to specific stimuli in the environment and only take place when such stimuli are present. For example, the need to avoid harm is only present when a threat is presented. Proactive needs, on the other hand, do not depend on stimuli in the environment. Rather, proactive needs occur spontaneously whenever they are aroused without the presentation of certain stimuli. For example, if a person becomes hungry, the individual will begin to look for food without influence from the external environment.

Personality Development in Childhood

Drawing from Freudian theory, Murray divided childhood into five developmental stages. Each stage influences individual personality by leaving a mark on it in the form of an unconscious complex. According to Murray, all people experience these five complexes because everyone goes through the same developmental stages. Each complex is posited to influence behavior and direct later development.

The first stage of development is known as the claustral stage. During this stage, the fetus in the womb is secure, at peace, and dependent. Complexes that may occur during this stage include the simple claustral complex, insupport complex, and the egression complex. The simple complex regards a desire to be in small, dark, and secluded places that make one feel safe and secure. Individuals with this complex are generally dependent upon others, passive, and are oriented toward behaviors that are safe and have proven effective in the past. The insupport complex regards individuals who experience feelings of insecurity that cause them to fear open places, drowning, tornados, fires, or any situation that requires mobility or change. The egression complex regards individuals who have a need to escape womblike conditions. For example, people with this complex may fear confined and restricted situations, and it will manifest itself by a preference for open places or mobility.

The second stage of development is known as the oral stage. The oral stage is associated with three accompanying complexes: oral succorance complex, the oral aggression, and the oral rejection complex. The oral succorance complex regards an amalgamation of mouth activities, passivity, and the need to be supported or protected. Manifestations of this complex involve behaviors such as kissing, sucking, eating, sympathy, and love. The oral aggression complex is a union of oral and aggressive behaviors. Manifestations of this complex may be biting, screaming, spitting, and sarcasm. The oral rejection complex regards behaviors such as vomiting, eating small amounts of food, seclusion, and avoiding dependence upon others.

The third stage of development is the anal stage and is associated with two complexes: the anal rejection complex and the anal retention complex. The anal rejection complex regards a preoccupation with defecation, anal humor, and feces-like substances such as dirt or mud. According to Murray, people with this complex are often aggressive and engage in activities such as throwing things, firing guns, or setting off explosives. Also, individuals who experience this complex are often dirty and disorganized. On the other hand, the anal retention complex is characterized by saving, collecting, cleanliness, and neatness.

The fourth stage of development is called the urethral stage and is exclusive to Murray's system. The urethral complex is characterized by extensive ambition, distorted self-esteem, bedwetting, and sexual cravings. This complex is sometimes called the Icarus complex, named after the Greek mythological figure that flew so close to the sun that the wax keeping his wings together melted. Similar to Icarus, individuals with the urethral complex aim their goals too high and consequentially experience failure and shattered dreams.

The fifth stage of development is called the genital, or castration stage. Murray dissented from Freud's view of this stage which posited that the fear of castration was the main source of anxiety for adult males. Rather, Murray held a more narrow view of this

castration complex. He contended that this complex is characteristic of a young boy's fantasy that his penis might be cut off. For Murray, this fear arises from masturbation in childhood and the parental punishment that could accompany it.

Murray's Later Years

After completing his book *Explorations in Personality: A Clinical and Experimental Study of Fifty Men of College Age*, World War II broke out. During the war, Murray served as a major in the Army Medical Corps and was eventually promoted to lieutenant colonel. Murray developed and organized an assessment program for the Office of Strategic Services, the predecessor of the CIA, where he assessed the psychological fitness of its agents. Murray's program would remain influential in the subsequent practice of personality assessment, especially in industrial-organizational psychology.

After the war, Murray returned to Harvard University. In 1947, at the age of 54, he received a tenured faculty position as well as the title of lecturer in clinical psychology. In 1951, Murray was named professor of clinical psychology. During these post-war years, Murray was influential in the formation of Harvard's interdisciplinary Department of Social Relations which combined the approaches of clinical and social psychology, sociology, and cultural anthropology. Murray retired from Harvard in 1962.

During this time, Murray developed a relationship with anthropologist Clyde Kluckhohn. Together, Murray and Kluckhohn coauthored a 1950 classic text of culture and personality entitled *Personality in Nature, Society, and Culture* (1953). The American Psychological Association (APA) eventually awarded him with Distinguished Scientific Contribution Award in 1961. Murray also received the Gold Medal from the American Psychological Foundation in 1969.

Murray became depressed after his wife's death, his retirement from Harvard, and Morgan's death in 1967. However, Murray found a new outlook on life when he married his second wife Carolina "Nina" Fish, who was co-director of the Psycho-educational Clinic at Boston University's School of Education. Murray's relationship and rich partnership with Fish led to fulfillment in his old age. Murray died of pneumonia on June 23, 1988, at the age of 95.

Overall, Murray's life contributions to American psychology made him a leading pioneer in the field. His unique interdisciplinary approach to psychology contributed to both its theoretical and practical advancement. Murray's seminal papers, theory, development of the TAT, and challenges to traditional schools of psychological thought reshaped the landscape of personality psychology. He left a rich and robust tradition of personology which personality theorists continue to study today.

Jack A. Naglieri

Larissa-Jayne Edwards and Ingrid K. Weigold

The University of Akron

Jack A. Naglieri, PhD, professor emeritus of psychology at George Mason University, is a prominent figure in the realm of intelligence assessment. After working closely with Alan Kaufman, and further developing his knowledge and expertise within the field of intelligence testing at the University of Georgia, he received his doctorate in educational psychology in 1979. Initially an assistant professor at Northern Arizona State University from 1979–1982, Naglieri next took a faculty position at Ohio State University from 1982–2000, where he was a professor of both school psychology and psychology, co-ordinator of the school psychology program, student advisor, and senior research scientist at the Nisonger Center. In 2000, he joined the faculty of George Mason University, where he was a professor of psychology, director of the school psychology program, and faculty member in their Center for Cognitive Development. He is currently a research professor in the Curry School of Education at the University of Virginia and a senior research scientist at the Devereux Center for Resilient Children.

Over the course of his career, Naglieri has developed numerous psychological tests, become a Fellow of the American Psychological Association's Divisions 15 (Educational Psychology) and 16 (School Psychology), and holds the status as a Diplomate in Assessment Psychology from the American Board of Assessment Psychology. Naglieri has received numerous awards for his work, including the Italian American Psychology Assembly Award for Distinguished Contributions to Psychology (2011), the Senior Scientist Award from APA's Division 16 (2001), the Ohio State University Faculty Research Award (2000), the Ohio School Psychologists Association Bartlett Award (1995), and the Arizona Association of School Psychologists President's Award (1981).

Naglieri is an avid researcher who has investigated several issues in the field of learning and education, including mental retardation, specific learning disabilities, giftedness, Attention-Deficit/Hyperactivity Disorder, IDEA and identification of specific learning disabilities, and cognitively-based mathematics interventions. In order to further understand testing differences among diverse populations, Naglieri has examined race, gender, and ethnic differences in cognitive processing. He has studied the fair assessment of diverse

groups by using non-verbal and neurocognitive processing tests, as well as examined the identification of gifted minorities. He has conducted psychometric studies of tests such as the Wechsler Scales of Intelligence, the Cognitive Assessment System, and the Kaufman Assessment Battery for Children. In recent years, Naglieri's scholarly pursuits have focused on the theoretical and psychometric issues concerning intelligence, cognitive interventions, and the diagnosis of learning and emotional disorders, as well as the theoretical and measurement issues related to the protective factors of resilience.

Naglieri's interest in intelligence testing was significantly influenced by his advisor, Alan Kaufman, at the University of Georgia during his graduate years. Kaufman's knowledge of and experience in test development helped to provide Naglieri with the necessary tools to establish his own tests. Naglieri's initial test publications include the Matrix Analogies Tests, the Draw-A-Person Quantitative Scoring System, and the Draw-A-Person: Screening Procedure for Emotional Disturbance. He has also published the Devereux assessments, including the Devereux Behavior Rating Scale-School Form, the Devereux Scales of Mental Disorders, the Devereux Early Childhood Assessments, and the Devereux Elementary Student Strength Assessment. He published the non-verbal General Ability Scale for Adults in 1997, which was later followed by several other non-verbal ability tests, including the Naglieri Nonverbal Ability Test-Multi Level Form, the Naglieri Nonverbal Ability Test Second Edition, and the Wechsler Nonverbal Scale of Ability. He published the first edition of the Cognitive Assessment System (CAS) in 1997 and published the second edition of the CAS in 2013. Other published tests include the Comprehensive Executive Function Scale and the Autism Spectrum Rating Scale.

Of all of Naglieri's work in test development, it is his collaborative efforts with J. P. Das on the CAS that has evolved into his most ambitious, well-known, and prominent scholarly work (see Naglieri, 2008). Specifically created for children ages 0–5 and 11–18, the premise for the CAS was to develop an intelligence test based on the findings of cognitive psychology and neuropsychology, particularly those of neuropsychologist A. R. Luria (Naglieri, 1996). Luria organized the cortex into two units, motor and sensory, with each of these units consisting of three cortical zones – primary, secondary, and tertiary. It was this model of cortical functioning that Naglieri and Das incorporated into the development of the CAS. The CAS is also founded upon the PASS cognitive processing theory. Its premise is based on the work of Luria and was later further developed by Naglieri, Das, and Kirby in 1994. The PASS outlines an information-processing framework consisting of four processes: planning, attention-arousal, simultaneous, and successive (Naglieri, 1996). These four processes address problem solving, focus, the organization and integration of information, and the memory of sequence or order, respectively, and are captured by the CAS subtests. Therefore, the CAS marks a shift from *g*-oriented measures of intelligence in that it is a measure of processes, not abilities.

The CAS consists of two subtests for each process in the core version of the CAS and three subtests for each PASS cognitive process in the extended version (Naglieri, 1996). The first process, planning, is used to devise and select strategies for problem solving and is captured by the CAS in such subtests as matching numbers and planned codes. The test-taker's strategies for problem solving are evaluated by the administrator through observation and the recorded responses. Attention is the mental process by which there is a selected

focus on a particular internal or external stimulus. Attention processes are measured by CAS subtests such as expressive attention and number detection. Simultaneous processing involves the organization of information into groups. Both non-verbal and verbal sorting is utilized to identify relationships between words and integrate logical and grammatical components of language. The CAS subtests for this section include verbal-spatial relations and figure memory. Successive is the last piece of the PASS theory and involves the memory of sequence or specific order. Word series, sentence repetition, and sentence questions are the CAS subtests that assist in recording this process.

The key benefits of the CAS, compared with traditional intelligence tests, lie in its ability to provide crucial information that aids in the development of educational interventions by highlighting the cognitive processes with which the individual struggles (Naglieri, 1996). This information helps teachers choose interventions for children with learning problems, identifies children with learning disabilities and/or attention-deficit/hyperactivity disorder, and fairly assesses children from diverse backgrounds. The fair assessment of individuals from diverse backgrounds, including different linguistic, racial, and ethnic groups, addresses a particular concern of test bias that intelligence testing has garnered from the public at large since the beginning of its use, making this a remarkable and important test development. Validity ratings of the CAS within minority groups have been found to be high, as have overall reliability ratings for the Core Battery Full Scale CAS within the general population (Naglieri, 2008).

As a result of Naglieri's contributions to the field of intelligence testing through test development, he has also made an impression on the clinical community by applying the knowledge he has gained during the years of test development to the creation of relevant clinical reference materials. These materials provide theoretical explanations of and practical instruction for the administration of some of his widely used tests. They further act as guides in the appropriate and responsible administration of tests that may have great impact on the educational course and development of the children they assess. Naglieri is the sole author of many publications, including *Essentials of CAS Assessment* (1999, 2008), and the first author or co- author of others, including *Assessment of Cognitive Processes: The PASS Theory of Intelligence* (Das, Naglieri, & Kirby, 1994), *Essentials of WNV Assessment* (Brunnert, Naglieri, & Hardy-Braz, 2009), and *Helping Children Learn: Intervention Handouts for Use at School and Home Second Edition* (Pickering & Naglieri, 2010).

Naglieri's contributions have changed the face of intelligence testing and ushered in updated and enhanced intelligence testing options. By applying empirically backed cognitive and neuropsychological research to his process of test development, Naglieri has been able to reinvent traditional methods of capturing intelligence data and, in the process, shape the future of intelligence testing.

Warren T. Norman

Stephanie L. Albertson

Indiana University Southeast

Warren T. Norman (1930–1998), professor emeritus of psychology at the University of Michigan, is a noted social psychologist recognized for advancing professional contributions to the structure of personality and innovative statistical procedures in personality assessment. Norman received a BS in mathematics (with distinction), and MA in statistics, and a doctorate in 1957, all from the University of Minnesota. He held many esteemed visiting professorships, fellowships, and lectureships during his long tenure at the University of Michigan, as with the Oregon Research Institute (1965–1966, 1987), the University of Birmingham in England (1972–1973), the University of Western Australia (1973), and the University of Queensland, Australia (1980). He served as chairman of the University of Michigan Senate and Head of its Department of Psychology. Norman served as the chairman for the Board of Scientific Affairs of the American Psychological Association, and was elected President of the Society of Multivariate Experimental Psychology. He was the youngest person to be appointed to these positions. He served on the Editorial Board for a number of publications, such as the *Annual Review of Psychology, Psychological Bulletin,* the *Journal of Applied Psychology,* and *Organizational Behavior and Human Performance.* He served as a panelist on many occasions for the National Science Foundation, the National Institute of Mental Health, and the U.S. Office of Education, as well as a member of the Research Committee for the Graduate Record Examination. His profound professional service contributions extensively focused on enhancing assessment measurements and testing parameters, which included the American Psychological Association (APA) Committee on Test Standards (1961–1962), the Committee on Test Reviewing of the APA Division of Evaluation, Measurement and Statistics (1964–1967), the APA Committee on Psychological Tests (1966–1967), the APA Committee on Assessment (1968–1969), and the APA Board of Scientific Affairs (1982–1985).

Norman wrote a number of distinguished articles contributing to the structure of personality and innovative procedures on personal assessment; these works have continued to grow in significance for the field of personality research. His 1963 article

in which he advanced a significant theoretical rational and empirical evidence for the "Five Factor Model" of personality (FFM), has become a classic, in personality psychology with citations continuing to increase even five decades after its publication. He further explored and researched the personality-descriptive terms listed by Allport and Odbert in the 1960s. Throughout this process, his objective was to develop a better structured and more rigorous classification of personality traits. He added some newer and more relevant terms and removed terms that had become antiquated. Psychology textbooks typically describe Norman's "Big Five" as the basic dimensions of personality, which is known as the most salient and scientifically compelling early example of what has come to be known as the Big Five factor structure. The key components of the Five Factor Model consist of the following: (1) personality has five dimensions, (2) scores on dimensions will fall along a normal distribution (bell curve), (3) personality is best described by individual traits rather than type groupings, (4) strength of individual scores indicates personality preferences, and (5) people scoring in the midrange prefer a balance of the two extremes for that trait. Norman recognized limitations in prior personality research, as in the conceptual sorting of the trait terms; therefore, he developed a new list of trait descriptive terms from the dictionary. He sets of terms into broad categories and focused his work on those terms that fell into the category he identified as biophysical traits. After considerable work to reduce the set of terms within this category to approximately 1,550 terms, he set out to formulate them. Initially, the terms were sorted into the endpoints of the five factors identified by Tupes and Christal (1961), culminating in 10 groups of words. He then sorted each of the 10 groups of words, which resulted in 75 groups of words. A factor analysis of scores on these groups produced the expected five factors.

The "Big Five" model of personality is a hierarchical arrangement of personality traits in terms of five basic measurements: extraversion, agreeableness, conscientiousness, neuroticism, and openness to experience. Highly extraverted individuals are confident and affable, rather than reticent and reserved. Agreeable individuals are collegial and affable, rather than hostile and impolite. Conscientious individuals are task-focused and orderly, as opposed to distractible and disorganized. Neurotic individuals are prone to experiencing negative emotions, such as anxiety, depression, and irritation, rather than being emotionally adaptable. Finally, highly open individuals have an extensive rather than limited range of interests, are perceptive rather than apathetic to art and beauty, and prefer novelty to routine. The Big Five/FFM was advanced to produce as much of the variability in individuals' personalities as possible, using only a limited set of trait dimensions. Many personality psychologists agree that its five dimensions capture the most important, fundamental individual differences in personality traits and that many other trait models can be analyzed in terms of the Big Five/FFM structure.

Most human personality traits can be condensed to five broad dimensions of personality, regardless of language or culture. These five categories were established by asking thousands of participants hundreds of questions, followed by a statistical factor analysis. It is essential to realize that the researchers did not intentionally search for five dimensions, but that five dimensions developed from their data analyses. In scientific circles, the Big Five is now the most widely accepted and used model of personality. Psychologists use this model of personality as the primary means for understanding and interpreting personality.

The Big Five, or the Five Factor Model of Personality is the most current, valid and reliable personality measurement presently available.

From the mid-1980s to the mid-1990s, the Five Factor Model of Personality (i.e. Big Five) was tested in academic and research communities worldwide and was found to be a superior model to earlier means of explaining and describing behavior. The "Big Five" structure was based on what is called the lexical hypothesis. Norman proposed a novel measure both for identifying impression management in self reports and for formulating scales that would be relatively immune to fabricating such response sets. He demolished what was then called "Deviation Hypothesis," in which subtle test content was equally as useful as obvious content in constructing self-report scales. He was the first to demonstrate the strong relationship between item face validity and empirical cross-validity. Continuing into the present, personality researchers have established the Five Factor Model as the basic paradigm for personality research. More recent comprehensive, digital studies have endorsed the existence of these five factors, demonstrating the variance in personality trait descriptors. To date, considerable research has implemented to substantiate the Big Five. Numerous Big Five questionnaire measures of the traits have been created, suggesting that the factors are not distinct to the study of trait descriptive terms. The five factors have been discovered in diverse cultures from across the world in both adjective and questionnaire analysis. And evidence suggests that they are, at least in part, heritable.

In the late 1950s, Warren Norman, while at the University of Michigan, learned of Tupes and Christal's work. Norman (1963) replicated the Tupes and Christal study, which supported the five-factor structure for trait taxonomy. This contribution is known throughout personality psychology as "Norman's Big Five," and currently referred to as the "Five Factor Model."

The two most outstanding contributions of personality assessment in the decades of the 1960s and 1970s were an article and a book chapter, both written by Warren T. Norman. Within the article, Norman provided in rigorous detail in both algebraic and verbal fashion an analysis-of-variance type of breakdown of the variances, covariances, and correlations that can be used to express facets of the relations among variables, subjects, and the critical interaction between the two. The most recent was proposed for the first time as the actual relation in which most scientists are interested, but which they hardly ever actually measure. This influential aspect of novel thinking predicted the model contribution of "Generalizability Theory" by Cronbach and Gleser, in addition to some of the applications of structural equation, or "causal" modeling.

Professor Norman educated numerous students in the discipline of personality psychology, and assisted many other psychology students in comprehending the technical obstacles of statistical and psychometric procedures. Norman was an internationally distinguished expert on personality structure and on the operation of pioneering statistical procedures in personality assessment. He wrote several seminal articles in these areas, publications that have continued to increase in significance within the field of personality research. Throughout the 1980s and continuing through the present, personality researchers have endorsed the Five Factor Model as the fundamental paradigm for personality research. Subsequent extensive, digital studies have supported the existence of these five factors that explain the variance in personality trait descriptors.

William Revelle

David M. Condon[1], Joshua Wilt[2], and Lorien G. Elleman[1]

[1]*Northwestern University*
[2]*Case Western Reserve University*

William Revelle is a professor of psychology at Northwestern University and an eminent scholar in the study of individual differences in psychological behavior. He earned his doctorate in 1973 from the University of Michigan and attained full professor status at Northwestern University in 1984. Over the last three decades, he has been a member of the Northwestern faculty, serving three terms as chair of the Department of Psychology. Although best known for his pioneering contributions to the development of public-domain tools for data collection and analysis, he has also published numerous influential works on personality theory and experimentally informed findings relating to a wide range of effects in personality, cognitive abilities, and situational determinants of motivation.

  Revelle was born in Washington, DC and raised in southern California. Given the influence of his father, Roger Revelle, a prominent oceanographer and a founder of the University of California, San Diego, it is no surprise that Revelle spent much of his youth near the water – surfing, sailing, and nurturing a passion for science. Revelle spent three of his teenage summers working on oceanographic expeditions, exploring the Pacific and mapping the ocean depths on small ships owned by the Scripps Institution of Oceanography. After early forays of study in mathematics and computer science (both of which have served him well throughout his career), Revelle settled on psychology as an academic major in his senior year of college, with the intention to apply theories of human and animal learning toward computational learning. Shortly after graduating from Pomona College in 1965, Revelle was wed to Eleanor McNown and the two of them moved to Sarawak, Malaysia where they were stationed as volunteers in the United States Peace Corps from 1965 to 1967. Among the many ways in which this experience shaped his thinking, his interest in personality science began in Malaysia, in part because the limited selection at the local English bookstore (100 km away in Brunei) included engaging paperbacks by Hans Eysenck. Motivated by the prospect of applying his knowledge of mathematics to the study of human behavior, Revelle matriculated at the University of Michigan in 1967 to

study among several of the thought leaders in psychology at that time. These included Jack Atkinson, Ted Newcomb, Warren Norman, Dick Nisbett, Clyde Coombs, and Donald Brown (his primary advisor). These mentors were largely dismissive of "situationist" claims against the existence of stable personality traits, and they encouraged Revelle's pursuit of personality research despite the prevailing sentiment of the era.

In 1973, Revelle completed his doctorate and moved with Eleanor and his two young sons from Ann Arbor to Evanston where he quickly established a vibrant research program. His early theoretical work focused on the interactive relationships between personality, motivation, and cognition. This included creative experimental designs and years of extensive theory-testing. In Revelle and Michaels (1976), both time pressure and caffeine-induced arousal were evaluated for interactive effects with Extraversion on tests of verbal ability. The results of this work had important implications for both personality as a field and for Revelle's subsequent research. While there was no evidence for main effects of Extraversion or caffeine on performance, there was evidence for a significant interaction between these variables. Caffeine improved verbal performance for extraverts and impaired performance for introverts. For personality, these findings supported the (now widely acknowledged) notion that the absence of a main effect for personality traits in various situations did not preclude their existence, stability, or predictive power. For Revelle's research program, they precipitated further efforts to specify a theory of how personality interacts with situational stressors to affect complex cognitive performance (Humphreys & Revelle, 1984), including the need to further account for the interactive effects of time of day (Revelle et al., 1980).

A separate but related theme of Revelle's theoretical work has followed from his desire to develop mathematical models of human behavior. These efforts were rooted in the contributions of his mentor and collaborator Jack Atkinson, though Revelle has proposed multiple extensions and refinements to Atkinson's Dynamics of Action theory (Atkinson, 1957) throughout his career (Revelle & Michaels, 1976; Revelle, 1982; Revelle & Condon, 2015). These models can be summarized simply as competing action tendencies which increase or decrease in intensity based on situational cues and consummatory behaviors, respectively. Mathematically, these action tendencies and the resultant action (behaviors) of the individual can be represented by a series of differential equations (the action tendencies), where the maximal action tendency is the behavior enacted by the individual (see Revelle & Condon, 2015 for some caveats).

More recent foci of Revelle's theoretical work have grown out of these earlier themes. One example relates to the development of public-domain, open-source tools for the assessment of cognitive abilities. The "International Cognitive Ability Resource" (ICAR; Condon & Revelle, 2014) uses mathematical models to automatically generate cognitive ability items. Revelle's first attempts at this resulted from the need for cognitive performance measures in his own experimental research on interactions between personality and motivation. The ICAR Project (icar-project.com) is now applying these same methods to encourage broader administration of cognitive ability measures (e.g. psychometrically robust, royalty-free assessment of cognitive abilities over the internet).

Revelle has also continued to generate and refine broad and integrative theories in personality psychology. Building on his earlier work that focused on dynamic models of behavior, he developed the idea that individual differences in personality traits may

be best understood as dynamic patterns of affect, behavior, cognition, and desire (or motivation) – the "ABCDs" of personality – over time and space (Revelle et al., 2016). This perspective has been applied to individual trait domains such as anxiety (Wilt et al., 2011) and Extraversion (Wilt & Revelle, 2009), and it has been put forward as a promising, overarching framework for the field of personality as a whole (Revelle et al., 2011). The first trait taxonomy emerging from this perspective delineated fundamental personality traits (Extraversion, Agreeableness, Conscientiousness, Emotional Stability, and Openness/Intellect) into their respective ABCD components (Wilt & Revelle, 2015).

In 2006, Revelle pioneered a new method of collecting personality data online in a project he called the Synthetic Aperture Personality Assessment (SAPA; sapa-project.org). Revelle's use of the term "synthetic aperture" refers to data collection techniques in radio astronomy in which signals from multiple telescopes are combined to simulate the resolution or sensitivity of a telescope several orders of magnitude more powerful. Unlike most personality assessments that give the same set of items to all participants, the SAPA method administers overlapping subsets of items. This allows for administration of very large pools of items without increasing the response burden for participants. The SAPA site collects data from more than 40,000 participants per year and is unique among research-based personality assessments in terms of the scope of individual differences being measured (including several thousand public-domain personality, cognitive ability and interest items).

In addition to creating this innovative assessment website, Revelle has developed a number of cutting-edge tools for data analysis, including several techniques which address the challenges inherent to data sets with planned missingness (the SAPA method produces data with massive missingness completely at random). These tools are freely available for use in the *psych* package (Revelle, 2017), which was developed in the statistical programming language R. Several of these tools are based on statistical techniques that Revelle himself invented. Revelle's Very Simple Structure (VSS) algorithm (Revelle, 1979) is implemented by the function "VSS." This is an exploratory method for determining the optimum number of interpretable factors to extract from a data set. Revelle has demonstrated (Revelle, 1979) that the VSS method is consistently more accurate than commonly employed psychometric rules (e.g. scree test, parallel analysis, eigenvalue of 1) in revealing the true number of factors in simulated data sets. Revelle's ICLUST algorithm (Revelle, 1979), implemented by the "ICLUST" function, is another useful exploratory method for examining the structure of items. ICLUST hierarchically clusters items using correlations corrected for attenuation and continues until either a specified reliability and/or a specified number of clusters is reached. One measure of reliability employed by the ICLUST function is one of Revelle's own, named Revelle's β (Revelle, 1979). This statistic quantifies the general factor saturation as the worst split-half correlation of a set of items. Other prominent analytic techniques implemented in the *psych* package include factor and principal components analysis functions with many options ("fa" and "principal"), item response theory-based techniques ("irt.fa" and "score.irt"), and measures of internal consistency and inter-rater reliability ("alpha," "omega," and "ICC").

In total, the *psych* package currently includes more than 400 functions for describing, cleaning, transforming analyzing, and graphing data. Since its first release in May 2005, *psych* has steadily grown in popularity to become one of the most frequently downloaded

R packages. The time, energy, and care needed to develop and maintain *psych* are a testament to Revelle's commitment to open science and to his broader advocacy for reproducible research (this refers to the scientific practice of sharing data, code, and instructions that allow others to recreate analyses as reported). The biggest beneficiaries of this commitment include the many thousands of R users in psychology (and a wide range of other scientific disciplines) who use the *psych* package for data analysis (without charge!) yet, many others have benefited from Revelle's frequent workshops, conference presentations, tutorials, and public-domain textbook on psychometrics; all of these are available for free download on his website (personality-project.org). Additionally, he has made data sets and code used in his published research freely available to the public (Condon and Revelle, 2015, 2016).

Revelle's many contributions have also resulted in his election as president of three different organizations: the Society of Multivariate Experimental Psychology, the International Society for the Study of Individual Differences, and the Association for Research in Personality. He is a fellow of the American Association for the Advancement of Science, the Association of Psychological Science, and the American Psychological Association and the Division 5 Representative to the APA Council. Revelle is also the former chairman of the governing board of the Bulletin of Atomic Scientists, an organization devoted to the preservation of mankind by the elimination of the existential threats of nuclear war, global climate change, and biological and cyber terrorism.

Despite his numerous and varied contributions as a scholar, there is, perhaps, no better indication of Revelle's worldview than the fact that he identifies first and foremost as a teacher – a view that is entirely consistent with his reputation. Thousands of undergraduates, hundreds of graduate and postdoctoral students, and innumerable professional colleagues view William Revelle as a mentor and this will likely be his most enduring and generous legacy.

Michael F. Scheier

Ellie David, Jared Whitmire, and Femina P. Varghese

University of Central Arkansas

Graduate School

Dr. Scheier received his BA in 1970 from the University of California at Berkeley and subsequently earned his PhD at the University of Texas in 1975. While at Berkeley, Dr. Scheier published three articles in the following journals, *Animal Behavior, Journal of Experimental Social Psychology,* and *Journal of Consulting and Clinical Psychology*. As an undergraduate, he worked at the Institute of Human Learning under Dr. Donald A. Riley. During graduate school, Dr. Scheier remained active in research by assisting Dr. Robert A. Wicklund and working under his mentor Dr. Arnold H. Buss, a leading researcher in aggression, temperament, self-consciousness, and shyness according to the University of Texas's website.

The first publication of Dr. Scheier's, coauthored by Warren and Riley in 1974, examined if there were systematic functions of octopi behavior during the pursuit of crabs. It was purported that the change in color of the octopi while pursuing crab was influenced by the surrounding environment. However, Scheier and his colleagues found that color change was not dependent on environmental stimuli, suggesting that octopi color change is associated with octopi movement (Warren, Scheier, & Riley, 1974).

Dr. Scheier's first principal investigation with co-authors Dr. Fenigstein and Dr. Buss explored how self-awareness affects aggression and their findings were published in 1974. Together they proposed an experiment that addressed the factors altering aggression. Interestingly, when subjects were exposed to a mirror reflecting their image, aggression decreased. Scheier, Fenigstein, and Buss (1974) found that the presence of an audience had little effect in reducing aggression. Conversely, when participants made eye-contact with the audience, there was a reduction in aggression (Scheier et al., 1974). Scheier's work highlighted the importance of men's self-awareness on aggression toward women. Furthermore, the results of this study support theories of self-awareness that persons are more likely to behave by their own standards when in a state of self-awareness, than that of others (Scheier et al., 1974).

One of Dr. Scheier's influential early graduate works was *Public and Private Self-Consciousness: Assessment and Theory,* where he coauthored the development of a scale to measure individual differences in self-consciousness (Fenigstein, Scheier, & Buss, 1975). The scale, which has been cited over 4,000 times on Google Scholar, has led to other research on self-consciousness. The development of the Self-Consciousness Scale was influential in understanding the differences between private, social, and public self-consciousness. For instance, those high in private self-consciousness may be contraindicated for insight therapy, but may benefit from other forms of therapy that engages the individual with the outside world (Fenigstein et al., 1975). The graduate work of Dr. Scheier was instrumental in the understanding of self-awareness and self-consciousness.

Dispositional Optimism

In 1985, Scheier coauthored "Optimism, Coping, and Health: Assessment and Implications of Generalized Health Expectancies" with Charles S. Carver in the journal of *Health Psychology*. The paper focused on the optimism scale Scheier and Carver created. The psychometric properties were verified by previous studies before testing the scale in the longitudinal research. Undergraduates completed three questionnaires a month before the end of the semester, evaluating optimism, self-consciousness, and a physical symptom checklist. The same questionnaire was administered on the final day of the academic semester. Results confirmed hypotheses that respondents indicating high levels of optimism were less likely to find the physical symptoms troublesome compared to those with low levels of optimism. Scheier and Carver (1985) found those with high private self-consciousness, people who focus on thoughts, feelings, and aspects of themselves, had a stronger relationship to this effect than those with low private self-consciousness.

Scheier's research on optimism was featured in a story in the *Atlantic*, in 2012 (Villarcia 2012) as their research stimulated research on the potential of positive thinking on physical and mental healing. The *Atlantic* reported that the optimism scale prompted more research related to dispositional optimism, with Scheier noting that the appeal of the optimism scale was that it was the first of its kind and it only had six items, making it more likely to be used, especially in large studies. Indeed, the 1985 paper has been cited over 3,000 times since its publication, and united two diverse fields, psychology with biology, according to the *Atlantic*.

Self-Consciousness Scale

In 1975, Allan Fenigstein, Arnold Buss, and Michael Scheier created the Self-Consciousness Scale. The scale is a 23-item questionnaire measuring public self-consciousness, private self-consciousness and social anxiety. Public self-consciousness refers to observable aspects of oneself. This includes the influence behavior and appearance have on the perceived impressions of others. Private self-consciousness refers to thinking about aspects of oneself not easily seen or criticized by others. Experiencing social anxiety is a subjective

experience centered on the apprehension of being scrutinized by others or doubting whether one is presenting an acceptable self.

In 1985, Carver helped Scheier revise the scale in response to criticisms. Two problems were addressed. First, non-college respondents, such as patients, did not understand the vocabulary. Second, non-college respondents found the format confusing. Scheier and Carver (1985) realized the questions were not intuitive for the respondents. Participants were asked to identify characteristics that were not representative of themselves, and then to what degree those characteristics were unrepresentative. Respondents struggled with this process of self-reflection.

To address the problem, Scheier and Carver's study investigated three groups ("coronary artery bypass patients, victims of strokes and their spouses, and healthy middle-aged women") (1985, p. 689) who completed the assessment. Participants indicated 15 items should be revised. Questions were adjusted to emphasize the primary idea and rephrased with simple language. Scheier and Carver (1985) made necessary revisions to improve the scale, and only one item was omitted.

Late Career

In his late career, Scheier continues to publish work and teach at Carnegie Mellon University. He has maintained interest in dispositional optimism and stressful life events. Recent research reflects his curiosity in human motivation, specifically the relationship between persistence and goal-directed activities. He investigates outcomes related to difficult life circumstances. This relationship has been observed in practical settings, largely within the health discipline. Some of his work has examined diagnoses such as breast cancer, associations with smoking cessation, and influences on sleep.

An example of a recent article on health is one that Scheier coauthored with Jobin and Wroschin (2014) examining the relationship between dispositional optimism and diurnal cortisol levels. Jobin, Wrosch, and Scheier (2014) controlled for the differences of perceived stress levels between optimists and pessimists to observe levels of cortisol secretion from participants' standard level of stress. The sample used responses from 135 older adults who were assessed for cortisol levels on a total of 12 days across six years. Results revealed a significant relationship between optimists and lower levels of perceived stress. Optimists did not have higher levels of cortisol, even on days they perceived as more stressful, in contrast to pessimists who showed an increase in cortisol secretion on days perceived more stressful.

Throughout Scheier's career, including recent years, he has conducted his work from the perspective of a personality psychologist. Scheier coauthored a textbook with Carver titled "Perspectives on Personality" in 1988, which is now in its eighth edition. The format of the book describes a different personality perspective and its real world application. Various personality perspectives from biological to psychoanalytic are presented. Newer perspectives such as genetics are also presented.

Scheier and Carver still work together investigating the effects of dispositional optimism. In 2014, they published an article reaffirming the physiological and psychological benefits of optimism. In the review, Scheier and Carver highlight greater optimism predicts greater

career success, better social relations, and better health. Scheier and Carver (2014) found all of the effects appear to increase the engagement of pursuing desired goals.

Michael F. Scheier has had a successful career. He holds memberships with the American Psychometric Association, American Psychological Society, and American Academy of Behavioral Medicine to name a few. He has received several awards from the American Psychological Association, was president of Div. 38 (Health Psychology) and recognized in 1998 as the recipient of the Outstanding Contribution to Health Psychology award. In 2007, he was given the Donald T. Campbell Award for his lifetime contributions in social psychology (Scheier, March 10, 2010). Scheier is a periodic reviewer for over 10 journals and sat on the advisory panel for social and development psychology in the National Science Foundation. He has authored 14 books (Scheier, March 10, 2010) and created five original scales (Carnegie Mellon of University, 2017). Scheier has impacted the field of psychology through his active investigation in dispositional optimism, the general expectancy that good things rather than bad will happen.

Mark Snyder

Megan E. Mansfield

Claremont Graduate University

Professor Mark Snyder, McKnight Presidential Chair in Psychology and director of the Center for the Study of the Individual and Society at the University of Minnesota, has marked his career by examining "how individuals create their own social worlds" (Dr Mark Snyder, n.d.). In doing so he has investigated the nature of both the play and its players – the social context and the nature of the self, consistently maintaining the dynamic relationship between the two. Since earning his doctorate from Stanford University in 1972, Snyder's work has been well recognized with accolades from his affiliated institution as well as leading professional associations in the field. Some of these recognitions include: Society of Experimental Social Psychology Dissertation Award (1973), the Donald T. Campbell Award for Distinguished Research in Social Psychology (SPSP, 2004), the Lifetime Career Award (International Society for Self and Identity, 2007), the Kurt Lewin Memorial Award (SPSSI, 2008), and the Distinguished Scientist Award (SESP, 2011) (Dr Mark Snyder, n.d.). Snyder has published numerous articles in prestigious journals and is marked as one of the most influential and impactful contributors to the field. This is also reflected in his well-regarded book *Public Appearances, Private Realities* (1987) and the various editorial positions he has held, including editor for *The Oxford Handbook of Personality and Social Psychology* (2012). In general, Snyder's research is categorized into three areas: the trait of self-monitoring, behavioral confirmation, and volunteerism. But across all of these areas his work has been at the forefront of important changes in the field, influencing and shaping its progress while focusing on the self in action.

If all the world is a stage, Snyder's work probes the question, what motivates people to act and why do they act as they do? People bring different motivations to their everyday social interactions, which influence their resulting behaviors. Some are cognizant of their social circumstances and adjust their external behaviors in hopes of fitting in with ease; others do not. Others are firm in their behaviors and opinions, seeing any deviations meant to please or appease someone else as unfaithful to their own dispositions and beliefs. Such persons prefer consistency between their internal and external selves. Snyder has termed this phenomenon self-monitoring, characterizing the former example (adjusting behaviors for

the context) as high self-monitoring. The latter example, maintaining a consistent external self, is considered characteristic of low self-monitoring. Snyder's book, *Public Appearances, Private Realities* (1987), focuses on this construct. Specifically, self-monitoring refers to the extent to which people observe and regulate their self-projections. As a result, it often moderates other traits, for example a high self-monitor who is also extroverted demonstrates extraversion only when it is appropriate for the circumstances. This construct is measured using the Self-Monitoring Scale and includes 25 true-false, self-descriptive statements, though a shorter version is also available (Snyder, 1972). The use of this construct has been applied to many different contexts such as the examination of the effectiveness of different advertising strategies (see Snyder & DeBono, 1985).

A key aspect of self-monitoring is an awareness of others and choosing to adjust behaviors based on what is observed. However, sometimes people are unknowingly impacted by the expectations of those with whom they interact. Snyder's landmark study, co-authored with Tanke and Berscheid (1977), examines the influence of those with whom we interact on our own behaviors and the breadth of such an impact. This process is termed "behavioral confirmation" and it impacts how one acts toward and responds to others. A particularly good example of the phenomenon, the 1977 study, was merely a starting point for a program of research that would continue for over a decade. Participant pairs were composed of previously unacquainted males and females who converse via telephone. Prior to the interaction the male partner was led to believe that their partner was either attractive or unattractive. The conversation between the partners was recorded and analyzed by objective, naïve observers. The researchers were interested in how the male partner treated the female partner given his expectations based on the false information of her attractiveness. The researchers were also interested in how the female participants behaved in response to the male partner's treatment. Snyder and colleagues determined that the female participants' behaviors confirmed the anticipations of the male participants, despite these being based on the presented information. In fact, the behaviors of the male participants also elicited the confirmation of their expectations. Snyder (1984) later claimed that people use their hypotheses about others to help guide behavior when interacting with people. Treating others as if those hypotheses are true helps simplify interactions but also elicits confirmatory behaviors. This work continued to build on the concept of the self in action, demonstrating that people are architects of their own environment and not merely responders to it.

Perhaps the most applied area of Snyder's work is in the realm of volunteerism. His work broadened the scientific inquiry into prosocial behaviors, expanding the helping behavior literature beyond questions of the existence of true altruism. Along with Omoto, Snyder began by defining volunteerism and creating a model for understanding it. For Snyder and Omoto (2008) volunteerism is a kind of social action defined by six characteristics: (1) voluntary, (2) not a reflexive act nor emergency helping, (3) done over a period of time, (4) payment is not received nor punishment avoided, (5) willingly sought out by volunteers and those they serve, and (6) acts are performed on behalf of others or causes. The model they use for understanding this phenomenon is termed the Volunteer Process Model (VPM) and it has been used in both lab and field work with a variety of methodologies as well as diverse populations and causes. This model includes four levels of analysis: Individual, Interpersonal/Social Groups,

Agency/Organizations, and Societal/Cultural. The model also includes three stages: antecedents, experiences, and consequences. Most investigations into the antecedent stage of volunteerism address the motivations people have for becoming volunteers. Later work articulated the nature of volunteer motivation as "agendas for action" meaning that different people have different agendas that they put into action. These agendas can change over time, thus motivation to action is not static. Such investigations have yielded three general themes of motivation: personal values focused (e.g. humanitarian concerns, religious values), community concerns (i.e. desire to aid specific communities), and self-focused concerns (e.g. networking, career experiences, making friends). Investigations in the experiences stage have demonstrated that a match between motivations for volunteering and actual volunteer experiences yields more satisfaction for volunteers and increases the likelihood that they will continue to volunteer. Research on the consequences stage of volunteerism has focused on how attitudes, knowledge, and behaviors change as a result of volunteering. Generally, volunteering has benefits for both individuals and the community at large.

Mark Snyder's work has greatly influenced the field of psychology, casting a long shadow over various domains of the field. The nature of what psychology is today is, in part, shaped by his work. In general his work can be characterized as an investigation into the self in action. Though the self has been studied for a long time, his investigations began a dynamic perspective on the self – examining the ways in which people are creators of their own realities and not just mere responders to their environment. In addition these works represent a complex interplay between the literatures of both personality and social psychology.

David Wechsler

Kara Eversole[1], Thomas Valentine[2], Cady Block[1], Laura Boxley[1], and Erica Dawson[1]

[1]*The Ohio State University Wexner Medical Center*
[2]*The Ohio State University*

David Wechsler, PhD (1896–1981), was a prominent Jewish American psychologist and scientist who is perhaps best known for his contributions to the conceptualization and evaluation of intellectual abilities across the lifespan. Wechsler was not born an American. Rather, his origins began in Lespezi, Romania on January 12, 1896. He was the youngest of seven children born to Moses Wechsler, a Hebrew scholar, and Leah Pascal, a local shopkeeper. Unfortunately, young Wechsler endured many hardships as a child. His home country was in the midst of famine, economic downturn, and growing anti-Semitism. The Wechslers relocated to New York City in 1902, but just four years later he had become an orphan. He was raised by his older brother Israel, who eventually achieved his own success and renown as a pioneer in neurology.

Education and Career

It was perhaps this combination of need for mentorship and guidance, and observation of his brother's success, that laid the groundwork for David Wechsler. He completed his Bachelor of Arts degree at the City University of New York (1916) and Master of Arts degree from Columbia University (1917) under Robert Woolworth. Here, his work focused on experimental psychopathology (Weiner & Craighead, 2010). However, Wechsler's curiosity and drive led him to seek a more applied experience. It was around this time that World War I was developing, a circumstance that led to Wechsler enlisting in the US Army. While awaiting his induction, he soon found a volunteer opportunity as a civilian scorer for the Army Alpha Test, the renowned group intelligence test administered to draftees. The Army Alpha Test was supervised by the Committee on the Psychological Examination of Recruits, which facilitated a first meeting between Wechsler and eventual mentors Edward Thorndike and Robert Yerkes.

Wechsler received his first assignment as an individual examiner for the Psychological Division of the Sanitary Corps at Fort Logan in Houston, Texas. In this role, Wechsler was tasked with administering the Stanford-Binet test to recruits who had performed poorly during group intelligence testing. However, the experience left him dissatisfied with the single score offered by the Stanford-Binet. It also convinced him of the limitations of current intellectual measures, which were designed predominantly for children and with an emphasis on verbal-intellectual functions. To Wechsler, these measures seemed less fair to adults, particularly those of foreign-born or lower education status who still functioned adequately as citizens.

In 1918, Wechsler received transfer orders to Europe. In 1919, he enrolled as an Army student at the University of London, where he conducted experiments in psychology under the guidance of Charles Spearman and Karl Pearson (Weiner & Craighead, 2010). Through this experience, Wechsler personally concluded that Spearman's general theory of intelligence (*g*) was overly restrictive, as it did not account for contributions from non-intellectual factors such as personality (Weiner & Craighead, 2010). Wechsler was officially discharged from service in August 1919, and shortly thereafter won a fellowship to the Sorbonne from 1920 until 1922. There, he studied the relationship between galvanic and emotional responses under the guidance of Henri Pieron and Louis Lapique – a topic that eventually influenced his doctoral research (Weiner & Craighead, 2010). In 1922, Wechsler returned to Columbia University to complete his PhD in experimental psychology, and published his dissertation, entitled "The Measurement of Emotional Reactions: Researches on the Psychogalvanic Reflex," in the *Archives of Psychology* in 1925.

Following graduation, Wechsler spent the next several years in a series of clinical positions that included private practice, the Psychopathic Hospital in Boston, and the Bureau of Child Guidance in New York City. During this period, he began to experiment with developing and using various types of tests. In 1926, for example, his *Tests for Taxi Cab Drivers* was used by the Yellow Cab Company of Pittsburgh. As acting secretary for the Psychological Corporation (1925–1927), he made publishing connections that would result in many of his subsequent intellectual measures.

In 1932, Wechsler assumed the role of Chief Psychologist at Bellevue Psychiatric Hospital. One year later, he joined the faculty of the New York University College of Medicine. He also met and married his first wife, Florence Felske. Unfortunately, hardship revisited Wechsler as Florence died tragically in an automobile collision just three weeks after their marriage in 1934. Wechsler devoted himself to his work, and just one year later had authored his first full text, *The Range of Human Capacities*, which he dedicated in her memory. In 1939, he again discovered love and married his second wife, Ruth Halpern. That same year, he published his first full measure, the Wechsler-Bellevue Intelligence Test. The couple went on to have two children, Adam and Leonard Wechsler.

As a result of his accomplishments at Bellevue and NYU, Wechsler served as a consultant for the US military during World War II and the Veterans Administration following the war. He remained on staff at Bellevue Psychiatric Hospital until 1967, and continued to serve as clinical professor of psychiatry at New York University School of Medicine until 1970. Though retired from clinical practice, he remained active academically and in humanistic endeavors. In recognition of his own Jewish heritage and its importance to him and his family, Wechsler worked with his brother Israel to fund the Hebrew University and

establish its psychology department. In 1947, Wechsler assisted in the development of a mental health program for Jewish survivors of the Holocaust (Kaufman, 2016). He also participated in the Wechsler Adult Intelligence Scale revision projects until his death at the age of 85 due to lung cancer. On May 2, 1981, Dr. Wechsler passed away in his home on the east side of Manhattan, New York City.

Legacy and Influence

The legacy and influence of Wechsler is an encyclopedia entry all on its own. In brief, he is widely considered to be one of the primary founders of clinical psychology. He was highly active as a leader in professional psychology. As noted above, from 1925 to 1927 he served as acting secretary of the Psychological Corporation, which led to the cultivation of publishing relationships that would result in many of his renowned measures. From 1959 to 1960, he served as the President of the American Psychological Association – a tenure that fundamentally altered its makeup from a predominantly experimental to a clinical psychological organization. He was also integral to the creation and organization of the American Board of Examiners in Professional Psychology, which fostered certification in clinical psychological specialties.

Prior to the introduction of Wechsler's measures, intelligence was widely conceptualized based on the use of individual mental age. Wechsler instead established the deviation quotient, conceptualizing intelligence as the amount of individual deviation around a mean score derived from one's representative peer group. This allowed for improved assessment of adult abilities that changed with age, and made it easier to detect abnormalities. Wechsler also rejected the concept of general intelligence as a single score, instead conceptualizing it across two main areas of verbal and non-verbal intelligence. He suggested the concept of *pattern analysis*, in which component subtest scores are compared to one another.

Wechsler's series of measures are still the most widely used today (Boake, 2002; Weiner & Craighead, 2010). They are also the most widely studied (Wahlstrom et al., 2012), and have been translated into over a dozen languages (Georgas et al., 2003). Wechsler's work was not only meaningful, but prolific: he authored more than 60 books and articles on the structure and evaluation of intellectual abilities. His most important texts include *The Range of Human Capacities* (1935), *The Measurement of Adult Intelligence* (1939), and *Non-Intellective Factors in General Intelligence* (1940). In a survey published in the *Review of General Psychology*, Wechsler was subsequently ranked as the fifty-first most cited psychologist of the twentieth century (Haggbloom et al., 2002).

David Wechsler has been recognized through numerous awards and honors during his lifetime, including the Special Award from the American Association on Intellectual and Developmental Disabilities (1972), Distinguished Professional Contribution Award from the American Psychological Association (1973), and an honorary doctorate from the Hebrew University of Jerusalem (1979). Posthumously, his family established the still active award program entitled the David Wechsler Early Career Grant for Innovative Work in Cognition through the American Psychological Foundation.

Though this entry represents an attempt at a brief review of his life and contributions to psychology, he is perhaps best understood and described by former mentee Alan Kaufman, PhD (Kaufman, 2016), who noted: "Dr. Wechsler possessed a rare blend of humility and

grandeur. From the first day I met him, he treated me with kindness and with a respect I had not yet earned. He was soft-spoken, yet every word was carefully measured and carried authority. He was a man of unusual compassion and unflagging integrity."

Contributor Biographies

Ola Mohamed Ali, MSc, is a clinical psychology graduate student at the University of Western Ontario, London, Canada. Her current research takes a developmental approach to investigating early emerging internalizing symptoms and their associations with structural brain abnormalities that could predict the development of anxiety disorders in later life.

Federica Andrei (PhD, Alma Mater Studiorum – Università di Bologna, 2015) is a clinical psychologist, postdoctoral fellow at the Department of Psychology of the University of Bologna, Italy, and a member of the Italian Psychological Association for the division of clinical and dynamic psychology. Her research interests include the development of personality and emotional intelligence. She is among the authors of the article entitled "The incremental validity of the Trait Emotional Intelligence Questionnaire (TEIQue): A systematic review and meta-analysis," published in the *Journal of Personality Assessment*.

Bostjan Antoncic (PhD, Case Western Reserve University, 2000) is Professor of Entrepreneurship at the Faculty of Economics, University of Ljubljana. His main research interests include corporate entrepreneurship/intrapreneurship, entrepreneurial networks, entrepreneurial personality, and international entrepreneurship. He has authored or co-authored various books (more than 10 of them in the area of entrepreneurship) and several scientific research articles. His papers have been published in academic journals such as *Journal of Business Venturing*, *Entrepreneurship and Regional Development*, *Industrial Management & Data Systems*, *Technovation*, *Transformations in Business & Economics*, *Journal of Business Economics and Management*, *Journal of Small Business Management*, and others.

Breanna E. Atkinson is a first-year PhD candidate in the Personality and Measurement Area of the Department of Psychology at the University of Western Ontario. Her research interests include personality and individual differences, behavioral genetics, measurement and data analysis, and test development. She has eight publications in peer-reviewed journals and has presented invited symposia and papers at conferences in Canada and around the world. The journals in which her publications appear include *Twin Research and Human Genetics* and *Personality and Individual Differences*.

Sarah E. Babcock is an MSc psychology candidate at the University of Western Ontario in the Personality and Measurement department. Her research interests include individual

differences, IQ assessment, scale development, resilience, and anxiety. Her recent publications include Babcock, S.E. et al. (2016) *Replications of an Investigation on Empathy and Utilitarian Judgement across Socioeconomic Status* (Submitted to *Scientific Data, Nature*). She also currently collaborates with the Pearson Clinical Assessment as a project co-ordinator for Canadian adaptations of intelligence and behavioral assessment tools.

Anjana Balakrishnan (MSc in psychology-personality and measurement, the University of Western Ontario, 2015) is a PhD candidate in social psychology at the University of Western Ontario. Anjana is a student affiliate of the Canadian Psychological Association and Society for Personality and Social Psychology. Her research interests lie in the study of international students, immigration, prejudice, how personality and culture interact to exert influence in life domains, and intercultural and interethnic relations.

Laura Borgogni, PhD, is full professor in Work and Organizational Psychology at the Sapienza University of Rome, Italy. Her research interests are related to goal setting, self-efficacy, and human development in the organizational setting. Her main publications are in journals such as *Applied Psychology: An International Review*; *European Journal of Work and Organizational Psychology*; *Work & Stress*; *Journal of Vocational Psychology*, and *European Journal of Psychological Assessment*. She is a member of the editorial board of the *Journal of Leadership and Organizational Studies* and *Organizational Dynamics*.

Emily N. Boughner is a current PhD student in Clinical Psychology at the University of Regina. Her research interests include examining factors that impact the relationships between experiences of interpersonal or betrayal trauma, mental and physical health, and trust in health care systems. She has been involved with research examining the maintenance of drug dependence in animals and relationships between posttraumatic symptoms, substance use behaviors, and mindfulness in humans. Her latest published research involved examining the relationships between traumatic experiences and the subsequent development of posttraumatic stress disorder or dissociation as mediated by individual differences in mindfulness traits.

Joshua S. Bourdage is an assistant professor in the Department of Psychology at the University of Calgary, specializing in Industrial/Organizational Psychology. Dr. Bourdage has investigated personality in relation to a number of critical behaviors and outcomes, including impression management, leadership, ethics, organizational citizenship, and sexuality. His work has been published in journals such as *Journal of Personality and Social Psychology, Journal of Applied Psychology, European Journal of Personality, Personality and Individual Differences,* and *Health Psychology*.

Richard E. Boyatzis is distinguished university professor and professor in the Departments of Organizational Behavior, Psychology, and Cognitive Science at Case Western Reserve University, and Adjunct Professor at ESADE. Having authored more than 175 articles, his books include *The Competent Manager,* and two international best-sellers*: Primal Leadership* with Daniel Goleman and Annie McKee; and *Resonant Leadership*, with McKee. His MOOC, Inspiring Leadership through Emotional Intelligence has now enrolled over 500,000 worldwide.

Gregory J. Boyle is a professorial fellow at the University of Melbourne. Previously, he served as professor of psychology at Bond University for over 20 years and was associate dean for research for several years. He is a fellow of the Australian Psychological Society, and the Association for Psychological Science. He has received the Buros Institute of Mental Measurements Distinguished Reviewer Award, and was honored with conferral of a higher Doctorate of Science degree from the University of Queensland. He has more than 200 publications, is co-author of a book on statistical methods, and is senior editor of several international psychology handbooks.

Ornella Bucci, PhD, is a member of both the International Research and Intervention Laboratories: Organizational Psychology for Vocational Guidance, Career Counseling, Talents and Healthy Organizations (WOPLabOProCCareerT&HO); Cross-Cultural Positive Psychology, Prevention, and Sustainability (IRILabCCPPP&S), directed by Professor Annamaria Di Fabio, at the Department of Education, Languages, Intercultures, Literatures and Psychology (Psychology Section). She has been the author of peer-reviewed articles and she has presented communications and posters at international and national conferences.

Emily R. Bunnett is a data analyst, researcher and PhD candidate at Swinburne University of Technology. Emily's areas of research include emotional intelligence, bullying, victimization, psychopharmacology, psychometrics and school social and emotional developmental programs. Emily is particularly interested in the use of advanced quantitative statistical analyses including structural equation modeling and is in the process of revising a measure of Ability EI in young children.

Bernardo J. Carducci, PhD, was professor emeritus of psychology and director of the Shyness Research Institute (http://www.ius.edu/shyness) at Indiana University Southeast and a Fellow of the American Psychological Association in Divisions 1: General Psychology, 2: Teaching of Psychology, 8: Personality and Social Psychology, and 52: International Psychology. He is the author of *The Psychology of Personality: Viewpoints, Research, and Applications* (3rd ed., 2015, Wiley) and *Shyness: A Bold New Approach* (2000, HarperCollins) and other books related to shyness translated into multiple foreign languages.

Silvia Casale, PhD, is associate professor of clinical psychology at the University of Florence. Her research interests include online social behavior, with a particular focus on interpersonal aspects of problematic Internet use, and the validity of grandiose and vulnerable subtypes of narcissistic character styles, with a particular focus on interpersonal outcomes. She is author of several papers related to the topic of internet addiction.

Edward C. Chang (PhD SUNY at Stony Brook) is a full professor of psychology and the director of the Perfectionism and Optimism-Pessimism (POP) Lab (https://sites.lsa.umich.edu/chang-lab) at the University of Michigan and a fellow of the Association for Psychological Science. He is the editor or co-editor of *The International Handbook of Positive Psychology* (forthcoming, Springer), *Cognitive-Behavioral Models, Measures, and Treatments for Depression, Anxiety, and Stress in Ethnic and Racial Groups* (forthcoming, American Psychological Association), *Positive Psychology in Racial and Ethnic Groups*

(2016, American Psychological Association), and *Handbook of Adult Psychopathology in Asians* (2012, Oxford University Press).

Covadonga Chaves (PhD) holds a Master's in Clinical and Health Psychology from Complutense University of Madrid. She was a visiting scholar at the University of Connecticut in 2013. She won the 2015 International Positive Psychology Association (IPPA) Award for the Best Dissertation. She is currently a full professor of psychology at Complutense University of Madrid. Her research interests focus on three areas: (1) the study of personal strengths, (2) growth experiences after adversity, and (3) the connection between positive emotions and health. She is currently involved in the development of positive intervention protocols in clinical and educational settings.

Samantha Chen is a second-year doctoral candidate in the Department of Psychology at the University of Western Ontario. Her research interests include perfectionism, psychological well-being, social support, and romantic relationships. Her PhD program is fully funded by SSHRC. Sam has four peer-reviewed journal articles and 13 conference presentations.

Kristi Chin (MSc, University of Western Ontario) is a currently a PhD candidate in Personality and Social Contexts Psychology at the University of Michigan. With her advisor, Dr. Robin Edelstein, she studies attachment, intimacy, and hormones and is active in school involvement as the sports chair of the Psychology Graduate Student Association.

Melina Claudius is a doctoral candidate in Counseling Psychology program in the Lynch School at Boston College. Her research interests are in the areas of trauma, immigration, risk and resilience in acculturation and topics at the intersection of psychology, social justice, and human rights. Her dissertation examines the role of social connectedness as a protective factor in the relationship between discrimination/trauma and psychological well-being among Central Americans.

Emma A. Climie, PhD, R Psych, is an assistant professor in the School of Psychology and Applied Child Psychology program in the Werklund School of Education at the University of Calgary. She is also the Lead Researcher for the Carlson Family Research Award in ADHD. Her research interests focus on a strengths-based understanding of children with ADHD and include resilience, mental health, stigma, and emotional well-being.

Kristina C. Conkright, BS, is a research associate at the Indiana University Southeast Shyness Research Institute and a graduate student in clinical psychology at Western Kentucky University.

Susan E. Cross is Professor of Psychology at Iowa State University. She is a Fellow of the Association for Psychological Science and the Society for Personality and Social Psychology. In addition to self-construal, her research interests include cultures of honor (with an emphasis on Turkey and Texas) and cultural conceptions of close relationships (with a focus on East Asia).

Dario Cvencek (PhD, University of Washington, 2007) is a research scientist at the University of Washington's Institute for Learning and Brain Sciences. Dr. Cvencek addresses early self-esteem from a developmental perspective using implicit and explicit

measures. His research emphasizes the role of self-esteem in the maintenance and formation of children's emerging identities, and examines how such processes might be facilitated by a tendency of the human mind to keep one's cognitions consistent with one another. Dr. Cvencek is one of the co-inventors of the Preschool Implicit Association Test (PSIAT) – an adaptation of the IAT for children between 3 and 6 years-old.

Rodica Damian is an Assistant Professor in Social-Personality at the University of Houston. Her current research examines the role of diversifying experiences and life events on personality development, and downstream consequences for creativity, success, and well-being. She studies these topics through a variety of methods ranging from historiometric to longitudinal studies. Dr. Damian has been awarded the Frank X. Barron Award Award by Division 10 of APA. She has published several articles in reputed journals, such as *PNAS* and the *Journal of Personality and Social Psychology*, and her research has been covered in national and international media.

Antonella Delle Fave, MD specialized in clinical psychology, is professor of psychology at the University of Milan, Italy. Her research work is centered on the study of well-being indicators, flow, and psychological selection across cultures and among individuals experiencing conditions of diversity and adversity. With an international team of researchers she recently launched the project "Eudaimonic and Hedonic Happiness Investigation," aimed at studying well-being components across cultures. She contributed to the development of positive psychology, as President of the International Positive Psychology Association (IPPA), the European Network of Positive Psychology (ENPP) and the Società Italiana di Psicologia Positiva (SIPP). Author of over 150 scientific articles and books, since 2010 she is editor-in-chief of the *Journal of Happiness Studies*.

Annamaria Di Fabio, PhD, is a Full Professor of Work and Organizational Psychology at the Department of Education, Languages, Intercultures, Literatures and Psychology (Psychology Section), University of Florence, Italy. She is the director of two International Research and Intervention Laboratories: Organizational Psychology for Vocational Guidance, Career Counseling, Talents and Healthy Organizations (WOPLabOProCCareerT&HO); Cross-Cultural Positive Psychology, Prevention, and Sustainability (IRILabCCPPP&S). She is associate editor of Personality and Individual Differences (PAID), editor-in-chief of the Section "Psychology of Sustainability and Sustainable Development" of the journal Sustainability (MDPI), editor of the journal Sustainability Science (in charge of the area "Psychology of Sustainability and Sustainable Development"), editor of Counseling Italian Journal of Research and Intervention.

She is the author of more than 200 peer-reviewed articles and of more than 100 books and book chapters. She has been elected since 2018 in the Board of Directors of the International Association of Applied Psychology (IAAP).

Aleksandar Dimitrijević, PhD in clinical psychology, is interim professor of psychoanalysis and clinical psychology at the International Psychoanalytic University, Berlin, Germany, a member of the Belgrade Psychoanalytical Society (IPA) and faculty at the Serbian Association of Psychoanalytic Psychotherapists (EFPP). He is editor or co-editor of 10 books or special journal issues as well as author of many conceptual and empirical papers about attachment theory and research, psychoanalytic education, psychoanalysis

and the arts. He is co-editor (with Gabriele Cassullo and Jay Frankel) of "Ferenczi's influence on contemporary psychoanalytic traditions" (Karnak, 2017).

David J. A. Dozois is a full professor of psychology and director of the Clinical Psychology Graduate program at the University of Western Ontario. His research focuses on cognitive vulnerability to depression and Cognitive Behavioral Theory/Therapy.

Michelle A. Drefs is an associate professor and director of training of the School and Applied Child Psychology program in the Werklund School of Education at the University of Calgary. Michelle has specific interests in psychoeducational assessment and the assessment and intervention of early mathematical abilities.

Amani M. Elrofaie holds an MA (education) in the field of education psychology from Western University's Faculty of Education. Her research focuses on childhood psychopathology and the effects of trauma and strength factors on mental well-being. Amani is currently an independent educational researcher with mixed-methods experience in technology, inclusive education, education policy, and school-based mental health intervention and prevention.

Amani Elrofaie is a policy analyst within the Government of Ontario Ministry of Education. She previously contributed research in the areas of child psychopathology, personality and individual differences, and education at the University of Western Ontario and in southwestern Ontario schools. Her current areas of research interest are child/youth mental health and well-being, as well as education policy. Among Amani's most noteworthy publications is her Master's dissertation on the internalizing symptoms of child victims of emotional trauma.

Anita Feher (MSc, University of Western Ontario) is a PhD candidate in psychology specializing in personality and measurement, with research interests in emotional intelligence, personality, conflict resolution, compassion, and health.

Laura K. Flanigan is a doctoral student in the School and Applied Child Psychology program in the Werklund School of Education at the University of Calgary. Her area of research focuses on factors that impact implicit and explicit stigma toward individuals with ADHD.

Callista Forchuk (BSc, University of Western Ontario) is an MSc candidate in psychology specializing in personality and measurement, with research interests in protective and risk factors for adolescent and adult psychopathology.

Maria Gerbino is associate professor of personality psychology at the Sapienza University of Rome. Her research interests include examining the role of different types of self-efficacy beliefs for adolescents' and young adults' development. She is the author of research articles related to the relations among emotional, interpersonal, and academic self-efficacy beliefs and youths' adjustment and well-being.

Marco Giannini is Associate Professor in Clinical Psychology at the Department of Health Sciences, University of Florence, Italy. A Psychologist and Psychotherapist, he has published many articles and books on methodology and measurement instruments.

Jacobus (Kobus) G. Maree (DEd, PhD, DPhil, University of Pretoria, 1986, 1992, 1997) is a full professor of educational psychology (www.kobusmaree.org) at the University of Pretoria and a fellow of the International Association of Applied Psychology in Division 16 (Counseling Psychology). A regular keynote speaker across the world, he has received numerous national and international awards and is the author of more than 90 peer-reviewed articles and 61 books or chapters in books since the beginning of 2008.

Alessio Gori, is a licensed psychologist and psychotherapist who obtained a PhD in Psychology at the University of Florence. He is actually assistant professor at the Department of Health Sciences of the University of Florence, president of the Integrative Psychodynamic Psychotherapy Institute (IPPI) and vice-president of the Italian Society of Psychological Assessment (SIPDC). He is author of many peer reviewed articles and has presented many communications and posters at international and national conferences.

Christina Gray is a doctoral student in the School and Applied Child Psychology program at the University of Calgary. Her research interests include exploring factors that contribute to resilience in children and adolescents with Attention Deficit/Hyperactivity Disorder (ADHD) as well as the inter-relationships between mind wandering tendencies and reading abilities within this population.

Anthony G. Greenwald (PhD, Harvard, 1963) is professor of psychology at the University of Washington. His recent research has been on implicit and unconscious cognition, especially applied to phenomena of stereotyping and prejudice and to mental processing of subliminal stimuli. He has received the Distinguished Scientist Award from the Society of Experimental Social Psychology (2006), the Lifetime Achievement Award from the Association for Psychological Science (2013), and the Award for Distinguished Scientific Contributions from the American Psychological Association (2017). In 1995, Dr. Greenwald invented the Implicit Association Test (IAT), which became a standard for assessing individual differences in implicit social cognition.

Andreas Hamburger is a psychoanalyst (DPG). He is professor of clinical psychology at the International Psychoanalytic University, Berlin, a Training Analyst (DGPT) and supervisor at the Akademie für Psychoanalyse und Psychotherapie, Munich, Germany. His current research includes Scenic Narrative Microanalysis, social trauma, psychoanalytic supervision, film analysis. His recent international publications are A. Hamburger (Ed.), (2015) *La Belle et la Bête – Women and Images of Men in Cinema* (London: Karnac); D. Laub and A. Hamburger (Eds.) (2017) *Psychoanalysis, Social Trauma and Testimony: Unwanted Memory and the Holocaust* (London, New York: Routledge); A. Hamburger (Ed.) (2017) *Trauma, Trust, and Memory* (London: Karnac).

Laura Henley graduated with an MSc from the School and Applied Child Psychology program at the University of Calgary. As a member of Dr. Emma Climie's Strengths in ADHD lab, Laura studied parent and child knowledge of ADHD and its impact on children's social and emotional development. Laura's research interests include ADHD knowledge and stigma, positive illusory bias, and resilience.

Emma R. Kahle Monahan is a Researcher at Chapin Hall at the University of Chicago. She graduated with her PhD in Social Welfare from the University of Wisconsin–Madison.

She graduated with a Bachelor's degree in Psychology from the University of Michigan, where she worked closely with Dr. Edward Chang in his Perfectionism and Optimism-Pessimism lab. She is broadly interested in how structural and historical factors like poverty, trauma, and social welfare policy affect family and child well-being.

James Kean is an associate investigator at the Centre for Human Psychopharmacology, directed by Professor Con Stough, at Swinburne University of Technology since 2014. He earned a bachelor of science in Psychology in 2008 at Deakin University, Melbourne, and an honors degree in Psychophysiology in 2009, at Swinburne University of Technology. He is currently earning a doctorate of philosophy in Science (Neuropharmacology), with a specific focus on child and adolescent neuroscience and complementary alternative medicine research. His work has been published in a number of international journals including *Psychopharmacology*, *Frontiers in Pharmacology*, *Phytotherapy Research*, *Complementary Therapies in Medicine*, *Nutrients*, *Nutrition Journal*, and *Journal of Alternative and Complementary Medicine.*

Maureen E. Kenny is a professor in the program in Counseling Psychology in the Boston College Lynch School, where she also recently held the position of Dean. Dr. Kenny completed her PhD in counseling and school psychology at the University of Pennsylvania and is a Fellow of Division 17, Society of Counseling Psychology, of the American Psychological Association. Dr. Kenny is the author of more than 50 articles in referred journals, seven books, and 25 book chapters. Her research interests focus on prevention and positive youth development, especially as related to career development, school engagement, and the development of social–emotional competencies.

Hans Henrik Knoop is an associate professor with distinction at Aarhus University, Denmark, and Extraordinary Professor at North-West University, South Africa. He is a founding member on the Board of Directors of the International Positive Psychology Association, and two-term President of the European Network for Positive Psychology. He is running the positive psychology research unit at the Department of Education, Aarhus University, having authored and co-authored more than 180 publications including nine books. His work on the measurement of well-being in education involves nation-wide studies involving up to half a million pupils.

Gaja Zager Kocjan is a researcher at the Slovenian National Institute of Public Health and a teaching assistant at the Department of Psychology, University of Ljubljana, Slovenia. Her main research interests include positive psychology and personality psychology.

Sylvain Laborde research focuses on understanding the role of cardiac vagal control (the activity of the vagus nerve, the main nerve of the parasympathetic nervous system, on the heart) in self-regulation at the cognitive, emotional, social, and health levels. He has also an interest in how personality, and in particular emotional intelligence, influences sports performance. In his leisure time, he is also fond of endurance sports (cycling, running, etc.) and loves playing the piano and singing with his band Enalkil.

Chloe Lau (BSc, University of Western Ontario) is a MSc candidate in the clinical psychology area, with research interests in predictors and risk factors for psychopathology.

Clara S. Lee is currently a PhD student at the University of Calgary, in the Department of Psychology specializing in industrial/prganizational psychology. Her Master's thesis examined faking on personality tests in a workplace context, and she has many research interests that are pertinent to personality in a workplace capacity, including organizational citizenship behaviors, impression management, interviews, and counterproductive workplace behaviors.

Irene López-Gómez (PhD) holds a Master's in research in psychology and a Master's in Cognitive Behavioral Therapy. She is a professor of psychology at the Rey Juan Carlos University of Madrid (Spain). She is additionally a researcher in the School of Psychology at the Complutense University, Madrid (Spain) and was a visiting scholar at the University of Pennsylvania in 2016. Her work is focused on understanding how psychological interventions work, developing evidence-based positive interventions and pursuing personalized interventions through controlled clinical trials. She has delivered lectures and published several research articles in peer-reviewed scientific journals on cognitive biases, positive affect, mood regulation and psychological interventions in mental disorders.

Yura Loscalzo Ph.D., is a licensed psychologist. Her main research interests are in Workaholism and Studyholism (a construct she developed during her Ph.D. studies) and their relationships with internalizing and externalizing disorders.

Richard N. MacLennan completed his PhD in 1989 at the University of Western Ontario also studying under Douglas N. Jackson. His area of specialization is psychological measurement and statistics. He is currently professor and head of psychology at the University of Regina. From 2004 to 2009, Richard led a joint SSHRC-Statistics Canada summer training workshop on using Statistics Canada datasets for statistical and GIS analyses. He has conducted some research in military psychology for the Department of National Defense, including taking a tour of Afghanistan in 2004. He has also undertaken some research in police psychology for the Royal Canadian Mounted Police.

Salvatore R. Maddi The son of Sicilian immigrants, Maddi was born in New York in 1933. He received a PhD in clinical psychology with honors from Harvard University in 1960. Having taught at the University of Chicago (1960–1986), and the University of California, Irvine (1986–2015), he has developed the hardiness approach, that shows how people can develop the courage, motivation, and capabilities to turn stressful circumstances into growth opportunities. He has won many awards, the latest of which is the 2012 American Psychological Foundation Gold Medal.

Marlies Maes is a postdoctoral researcher at KU Leuven, Belgium. Her research interests include adolescent loneliness, peer relationships, victimization, and cultural differences. She has conducted several psychometric studies on loneliness measures and is currently working on several meta-analyses about loneliness.

Eiko Matsuda (PhD, Ochanomizu University, 2003) is a full professor of clinical and personality psychology at Toyo University and executive Director of the Japanese Society of Personality Psychology (http://jspp.gr.jp). She specializes in sleep disorders and Cognitive Behavioral Therapy.

Moïra Mikolajczak is assistant professor at the University of Louvain (Louvain-la-Neuve, Belgium). Her main line of research concerns emotional competence and emotion regulation, which she studies from both fundamental and applied perspectives. Examples of recent noteworthy publications are: M. Mikolajczak et al. (2015). A nationally representative study of emotional competence and health. *Emotion*, *15,* 653–567; J. Quoidbach, M. Mikolajczak, & J. J. Gross (2015). Positive interventions: An emotion regulation perspective. *Psychological Bulletin*, 141, 655–693; A. Pena-Sarrionandia, M. Mikolajczak, & J. J. Gross, (2015). Integrating emotion regulation and emotional intelligence traditions: A meta-analysis. *Frontiers in Psychology, 6*, 160, 1–27.

Mariella Miraglia, PhD, is a lecturer in organizational behavior at Norwich Business School, University of East Anglia, Norwich, UK. Her main research interests lie in the field of organizational behavior, human resource management, and occupational health psychology. She is particularly interested in absenteeism and presenteeism (i.e. working while ill) in organizations. Her studies have been published in international journals, such as *Journal of Occupational Health Psychology*, *Journal of Vocational Behavior*, *Human Relations*, and *Human Resource Management*.

Emma Mosley research interests lie within individual differences in performance under pressure. Emma has expertise in heart rate variability and its use for the measurement of stress and self-regulation under pressure. She also has a particular interest in personality-trait-like individual differences and how they affect athletes in stressful situations.

David B. Mykota is a professor in the College of Education, Department of Educational Psychology and Special Education, at the University of Saskatchewan. He is a Research Associate with the Community University Institute for Social Research and his research interests include substance use, psychopathology, program evaluation, resilience, e-learning, and cultural/indigenous psychology.

Rebecca Nowland is a research fellow working in the Centre for Mental Health and Safety, University of Manchester, UK. She has published a number of papers that examine predictors and health implications of loneliness.

Jessica K. Padgett is an MSc candidate in psychology at Western University. Her current research focuses on masculinity studies, particularly variations in and alternative forms of masculinity. She is interested in using mixed methods to assess how masculinity is formed, how it varies between groups and individuals, and how it influences socially relevant attitudes, values, and behaviors.

Letizia Palazzeschi, PhD, is a researcher at the Department of Education, Languages, Intercultures, Literatures and Psychology (Psychology Section), University of Florence, Italy. She is a member of both the International Research and Intervention Laboratories: Organizational Psychology for Vocational Guidance, Career Counseling, Talents and Healthy Organizations (WOPLabOProCCareerT&HO); Cross-Cultural Positive Psychology, Prevention, and Sustainability (IRILabCCPPP&S), directed by Professor Annamaria Di Fabio, at the Department of Education, Languages, Intercultures, Literatures and Psychology (Psychology Section), University of Florence, Italy. She has been the author of

many peer-reviewed articles since 2005 and she has presented many communications and posters at international and national conferences.

Ronald S. Palomares (PhD, Texas A&M University, 1992) is an associate professor in psychology at Texas Woman's University. His current research interest focuses on examining the positive impact on military-connected children who grew up with a parent serving in the military and also teaching and serving the profession of psychology. He maintains a part-time psychology practice serving the needs of residents in a long-term care/rehabilitation facility. He previously worked at the American Psychological Association as an Assistant Executive Director in Practice (2000-13). He presently serves on the Texas psychology licensing board and was awarded both the Texas A&M College of Education & Human Development Outstanding Alumni Award and knighted in the Brandenburg Bailiwick of the Knightly Order of Saint John of the Hospital of Jerusalem (Johanniter Order).

James D. A. Parker received his PhD in Psychology from York University (Ontario). He was a research fellow in the Department of Psychiatry at the University of Toronto before joining the Department of Psychology at Trent University (Ontario, Canada) in 1994. Professor Parker has published over 160 articles and book chapters, mostly in the areas of emotion, health, and wellness. He is co-author of *Disorders of Affect Regulation* published by Cambridge University Press, the *Handbook of Emotional Intelligence* published by Jossey-Bass, and *Assessing Emotional Intelligence* published by Springer.

Sampo V. Paunonen (1952–2015) obtained all of his degrees in psychology from the University of Western Ontario (now Western University), studying under Douglas N. Jackson. "Sam," as he was better known, also spent most of his professional career at Western. He was a highly respected personality researcher, and was well-known as a trait-theorist which is rare these days. Sam developed an innovative nonverbal measure of personality using stick-figure drawings, which he used to undertake cross-cultural studies of personality. After writing this encyclopedia entry, Sampo Paunonen died after a sudden illness on December 29, 2015, at the age of 63.

Juan-Carlos Pérez-González (PhD, UNED, 2010) is associate professor of education and founder and director of EDUEMO, Emotional Education Lab (www.eduemo.com) at Universidad Nacional de Educación a Distancia (UNED) in Spain. He is a fellow of the International Society for the Study of Individual Differences (ISSID) and of the International Society of Research on Emotion (ISRE). His research focuses on assessment and education of emotional intelligence, social and emotional learning and personality.

Naomi L. Perry (PhD, Swinburne University, 2015) is clinical trials co-ordinator at the Centre for Human Psychopharmacology, Swinburne University of Technology. After completing her PhD investigating the effects of soy isoflavones on premenstrual symptoms and cognitive function, she has continued working in the area of nutraceuticals and cognition. Naomi is currently involved in research using state-of-the-art methodology including brain imaging techniques to understand the neurocognitive effects of nutritional and dietary interventions. She is co-author of "Adaptogens" (in *Evidence-Based Herbal and Nutritional Treatments for Anxiety in Psychiatric Disorders*, 2016, Springer) and

several peer-reviewed journal articles related to the use of natural therapies for cognition and sleep.

Konstantinos V. Petrides is director of the London Psychometric Laboratory and Professor of Psychology and Psychometrics at University College London (UCL). He is the developer of the family of Trait Emotional Intelligence Questionnaires (TEIQue), which are used in commercial and scientific research applications globally. Konstantinos lectures internationally on his theory of trait emotional intelligence, personality, and psychometrics. The academic website of the London Psychometric Laboratory can be accessed at www.psychometriclab.com.

Rachel A. Plouffe is a current PhD student at the University of Western Ontario in London, Canada. Rachel's current research interests are in statistics, psychometrics, personality questionnaire development and validation, and the Dark Tetrad of personality. Rachel has authored four peer-reviewed journal articles and has presented 13 conference posters.

Pamela Qualter is a professor of psychology for education at the University of Manchester, UK. She has published many papers that examine the predictors of prolonged loneliness during childhood and adolescence. She also researches emotional intelligence during childhood and adolescence, and has designed a number of interventions to increase emotional and social skills.

Kilian J. Ramisch is a graduate student at the University of Heidelberg. He received his BSc in psychology at the University of Bamberg and is a visiting student researcher at the German Sport University Cologne. Kilian is particularly interested in psychophysiology, cognition, and the psychology of international relations. In his spare time, he is a passionate runner and outdoor enthusiast.

Katerina Rnic is a PhD candidate in the clinical psychology program at the University of Western Ontario. Her research interests include cognitive vulnerability, stress generation in depression, and how cognitive and behavioral vulnerabilities relate to the generation of and response to depressogenic life events, particularly those involving rejection.

Jérôme Rossier is currently full professor of vocational and career counseling psychology at the Institute of Psychology of the University of Lausanne. He is the editor of the *International Journal for Educational and Vocational Guidance* and member of several editorial boards of scientific journals such as the *Journal of Vocational Behavior* and the *Journal of Research in Personality*. He recently co-edited the *Handbook of Life Design: From Practice to Theory and from Theory to Practice*. He has participated actively in many international research projects, such as the international career adaptability project.

Ken J. Rotenberg is a professor in the School of Psychology at Keele University. He is a developmental psychologist and social psychologist and specializes in social development. He has published two books on the topic of interpersonal trust and is an author of around 40 papers on that topic.

María-José Sánchez-Ruiz Dr. Maria-Jose Sanchez-Ruiz is an associate professor of psychology at the Lebanese American University. She has also worked extensively with the trait

emotional intelligence program at UCL, where she was recently appointed as an Honorary Senior Research Associate. She has worked extensively in the field of individual differences, and particularly creativity and emotional intelligence. She is an associate editor of Frontiers and peer-reviewer of other reputable journals. She has published empirical work in high impact-factor journals and some of her papers have been widely cited (e.g., "Developments in trait emotional intelligence research" published in Emotion Review, Q1). She is currently interested in emotional intelligence and character strengths training.

Catalina Sarmiento (BSc, University of Ottawa) is a MSc clinical psychology candidate at the University of Western Ontario, with research interests in access and use of children's mental health services.

Gabriela Sheinin gained her BSc at Trent University where she completed a thesis on academic success and emotional/social competency in older adolescents. She is currently a graduate student in the Department of Psychology at the University of Windsor (Ontario, Canada).

Erin J. Shumlich, MSc, is a PhD student in clinical psychology at the University of Western Ontario. Her clinical work incorporates mindfulness-based techniques and third-wave cognitive behavioral approaches. Her research interests include sexual consent, sexual assault, and criminal behavior.

Alex B. Siegling completed his PhD in 2015 at University College London, where he remains involved as a research associate. His PhD gave rise to a new psychometric method for refining multi-faceted assessment instruments, called "Facet Benchmarking" (initially presented in Siegling, Petrides, & Martskvishvili, 2015). His current academic focus is on the theory and measurement of drive. Alex has also worked in R&D and consultant capacities in industry, frequently for publishers of leading psychometric tools.

Vanessa M. Sinclair is a Ph.D. candidate at Western University in the Social, Personality, and Developmental Psychology area. Her main areas of research are personal strengths, as well as the measurement, antecedents, and consequences of political attitudes.

Martin M. Smith is a third-year doctoral candidate in the Department of Psychology at the University of Western Ontario. His research focuses on the assessment of perfectionism and the role perfectionism plays in mental disorders such as depression. Since 2014, Martin has published 18 peer-reviewed journal article and three book chapters. Martin has also participated in six symposia and presented over 20 posters. His research is nationally funded and his work has garnered academic awards such as the Kenneth Deon Award for Best Master's thesis. Martin is also an associate editor of *Personality and Individual Differences*.

Martin M. Smith (MSc, Western University) research is focused on the role of personality traits and social processes in psychopathology. In particular, he has studied the contribution of perfectionism to depression. Martin's research involves innovative methodologies (e.g. experiencing sampling), and advanced statistics (e.g. bifactor modeling; multilevel modeling; meta-analysis). Additionally, Martin has published 18 peer-reviewed scientific articles (11 first-authored), three book chapters, and presented several symposia.

Caitlin J. Spencer is a recent MSc graduate from Western University and is currently working on campus at the International and Exchange Student Centre. Her research interests include self-concept and emotional intelligence (EI) in children and adolescents. She has recently completed a thesis entitled "An extension of the Dimensional Comparison Theory: A Test of Emotional Intelligence Self-concepts" (2016), and has been invited to co-author a chapter regarding developmental considerations in EI in the forthcoming *Handbook of Emotional Intelligence*, edited by K. V. Keefer, J. D. A. Parker, and D. H. Saklofske.

Sarah C. E. Stanton is a lecturer (assistant professor) in the Department of Psychology at the University of Edinburgh. She uses a social psychology approach to understand the cognitive and affective aspects of close relationships and their effects on behavior, physiology, and health and well-being. She is particularly interested in how promoting positive relationship experiences benefits closeness to others immediately and over time. Her expertise lies in a theoretically-driven, multi-method approach to studying close relationship dynamics.

Yoshiyuki Tanaka (MA, Clinical Psychology, Kurume University, 2003) is an associate professor of psychology at Kyoto Tachibana University. He collaborates with Dr. Tsuda on several research projects, and has published papers that focused on various aspects of positive psychology, mental health, and so on. He is on the board of trustees of the Japanese Association of Health Psychology, and the Japanese Society of Stress Management.

Gillian C. Tohver (MSc, University of Western Ontario) is a PhD candidate in psychology specializing in personality and measurement, with research interests in personality and longitudinal health and coping.

Paul F. Tremblay is an assistant professor of psychology at Western University who has published a number of articles on human aggression focusing on trait aggression and alcohol-related aggression. His current work focuses on improving curriculum for engaging students in advanced statistical and research methods courses.

Akira Tsuda (PhD, Kurume University, 1986) is a full professor of psychology at Kurume University and director of the Japanese Association of Behavioral Sciences (http://www.jabs.jp). He has received several awards from the Japanese Society of Stress Sciences, the Japanese Association of Existential Therapies, and the Japanese Association of Behavioral Medicine.

Carmelo Vázquez (PhD) is professor of psychopathology, at the Complutense University in Madrid. He was a postdoctoral Fulbright visiting scholar at Northwestern University (USA) and received the "Annual Award for Early Distinguished Scientist" in 1997. He has published more than 150 papers in top-ranked journals. He is a member of the editorial board of several international journals, the past-president of the Spanish Society of Positive Psychology (SEPP), the past-president of the International Positive Psychology Association (IPPA), and a national representative of the European Network for Positive Psychology (ENPP). He collaborates as an external advisor to the crisis intervention team of Doctors Without Borders.

Philip A. Vernon is professor emeritus in the Department of Psychology at the University of Western Ontario. His research interests include behavioral genetics, intelligence and

cognitive abilities, and personality and individual differences. He has edited three books, has over 150 publications in peer-reviewed journals, and has presented at conferences around the world. The journals in which his publications appear include *Intelligence*, *Personality and Individual Differences*, and *Psychological Bulletin*. He is past-president of the International Society for the Study of Individual Differences and served as editor-in-chief for *Personality and Individual Differences*.

Melanie Jordan Wheatley has completed her Bachelor of Arts with an honors specialization in psychology at Western University and is currently a candidate in the Clinical Trials Management Diploma program also at Western. Her research has focused on children's mental health service utilization, and she continues to explore her passion for research in health-related fields.

Gabrielle Wilcox is an associate professor in the School and Applied Child Psychology program. Her research interests include school mental health, supporting transitions, using neuropsychological assessments to inform intervention, educational neuroscience, and clinical reasoning.

Claire A. Wilson is a PhD candidate at the University of Western Ontario in the Psychology Department. Her current areas of research include resiliency and other psychological predictors of successful aging in older adults. In addition she conducts ongoing research examining the psychosocial predictors of academic performance and completion rates of university undergraduate students. A recent publication is C. A. Wilson and D. H. Saklofske (2017). "The relationship between trait emotional intelligence, resiliency, and mental health in older adults: The mediating role of savouring," *Aging and Mental Health*. Advanced online publication, doi:10.1080/13607863.2017.1292207.

Harriet Winterflood graduated from the University of Calgary's School and Applied Child Psychology program. She is currently a provisional psychologist in Manitoba, Canada. Her research interests include examining the relationship between developmental strengths, school bonding and academic achievement, specifically within a Canadian Aboriginal population.

Elizabeth A. Yu is a PhD student on the Clinical Science program at the University of Michigan, Department of Psychology. Her research interests include examining social and personality factors that affect mental health. She is especially interested in studying the function of meaning in life, sources of meaning in life, and positive cognitions as correlates and predictors of psychological adjustment and well-being. Key to her research interests is the consideration of culture and context, especially in ethnic minority populations. More generally, Elizabeth is interested in identifying predictors of adjustment in different racial/ethnic groups and their implications for clinical and counseling psychology.

Tina Yu is an undergraduate student at the University of Michigan, Department of Psychology. Her research interests include examining the role that positive future cognitions may play in the quality of adjustment and mental health in adults. She is also interested in sexual assault and trauma, chronic illness, ethnic/racial psychology, and the specific effects of culture and context on psychological and physical adjustment, especially in Asian/Asian American populations.

Melissa Yue is a full-time graduate student at the University of Calgary in the School and Applied Child Psychology program in the Werklund School of Education. She holds three BScH undergraduate degrees with honors in Biology, Health Sciences, and Psychology. Her research interests include child development and strength-based models of intervention. She is currently a researcher in the Strengths in ADHD lab at the University of Calgary.

Lynne Zarbatany is an associate professor of psychology at Western University who studies peer influences on children's social development and psychological adjustment. Her work aims to identify supportive and socializing processes involved in friendships and peer clique membership, as well as individual differences in children's peer experiences, including bullying and victimization.

Moshe Zeidner is professor of educational psychology and human development at the University of Haifa, Israel. His main fields of interest are in the area of human emotions, personality and individual differences (with particular concern for the interface of personality and intelligence), emotional intelligence, positive psychology, test anxiety, and the stress and coping process. He is the author or co-editor of 10 books and author of over 250 scientific papers and chapters. His co-authored book on *What we Know About Emotional Intelligence* received the PROSE award for 2009.

Sabrina Zirkel, PhD, is dean of the School of Education and Counseling Psychology at Santa Clara University. Her areas of research concern issues of race, ethnicity, gender and class in education and the role of educational contexts in improving the educational outcomes of under-represented students.

My dad, Professor Bernardo "Bernie" Carducci, had a passion for life. He loved being a dad, celebrating Italian culture and community, and talking cigars with friends at the local smoke shop. My dad also loved psychology – teaching psychology, researching psychological phenomena, and raising awareness of the power and promise of an undergraduate psychology degree. He was an excellent teacher, scholar, and mentor who never lost sight of his roots as a first-generation college student, committing numerous hours and energy in support of student success. To those who knew my dad, it was no surprise. He was a personality psychologist. My dad had a BIG personality, evident in his bright ties, Hawaiian shirts, and zest for life. He was passionate about the study of personality and experienced tremendous joy in his life's work, the study of shyness. My dad was honored to be selected as editor of the latest volume of the *Wiley Encyclopedia of Personality and Individual Differences* and frequently shared with me his enthusiasm for the project. Although his unexpected passing prevented him from shepherding the book through the final stages of publication, I know he would be proud of the final product and wish to express his gratitude to all contributors and editors. I would like to extend a special thank you to Chris Nave for his willingness to assume editorial responsibilities of this volume upon my dad's passing.

Dad, I love and miss you very much. Congratulations on the publication of this volume!

Rozana Carducci

Adaptability

Jérôme Rossier

University of Lausanne

Definition and Emergence of the Construct

Adaptability is usually conceived as the psychological capacity that allows people to adapt, in a constant, dynamic, and dialectic interaction with the environment. This adaptation is understood in terms of mutual adjustment and recognition. It may occur within close interpersonal relations or within larger social structures or organizations. Adaptability has been linked with the Freudian notion of regression; adaptive regression is a shift from the ability to delay immediate gratification and a lack of mobility to immediate gratification and flexibility. It might promote several adaptive behaviors such as problem-solving skills and creativity. Adaptive capacity was also an important aspect of Jean Piaget's (1896–1980) theory of cognitive development. According to his view, the cognitive system is adaptive when assimilation and accommodation processes are balanced and when both are equally effective. The importance of an unstable equilibrium was already central in Claude Bernard's (1813–1878) and Walter Bradford Cannon's (1871–1945) notions of homeostasis, the property resulting from a cycle of disruption and reintegration allowing adaptation to internal and external changes. Adaptation, and thus adaptability, is also a product of evolutionary processes.

Nowadays adaptability is usually conceived as a psychological means that sustains adaptive behaviors allowing one to face and manage stressors and to promote an adjustment between a person and its environment (P-E fit). Both adaptability and coping are constructs that contribute to regulate the expression of contextually adapted behaviors and affect. Savickas (1997) claimed that adaptability is a crucial competence in a contemporary world, since it fosters the ability to handle insecurity and to manage our lives and careers. In this context, adaptability increases people's tolerance of uncertainty and ambiguity, and helps them to evolve in a dynamic and boundaryless context.

Adaptability is considered as one of the four levels of adaptive functioning. First, people differ according to trait-like dispositions (also referred to as proneness to adapt), or their predisposition to adapt depending of their level of *adaptivity* or flexibility. Second, in order

to adapt, people have to be able to use and activate regulation processes that are psychosocial resources, called *adaptability* (or abilities to adapt). Third, when people express adaptive responses, such as orientation, exploration, or self-management behaviors, they are *adapting*. Finally, adaptive functioning or *adaptation* occurs if the P-E fit is satisfactory for the environment and satisfying for the person. According to this perspective, adaptability is a set of important regulation processes underlying adaptation.

Adaptability and Dispositions

Adaptability and Personality

Michael Kirton developed his adaptive-innovative theory in the 1970s to describe the problem-solving styles of executives, managers, and leaders. He distinguished on one end of a continuum people who prefer to "do things better," and on the other end people who prefer to "do things differently." Both styles are adaptive, but doing things differently requires more creativity and the use of new, original, and culturally acceptable problem-solving strategies. These cognitive styles are considered as consistent individual differences and are known to relate meaningfully with the Big Five personality dimensions. The adaptive-innovative dimension correlates positively with extraversion and openness to experience, and negatively with conscientiousness. Moreover, decision-making performance in a changing workplace seems to be positively associated with openness, and negatively with conscientiousness. On the contrary, when considering adaptability as a set of adaptive abilities from a psychosocial perspective, it is negatively associated with neuroticism and agreeableness, and positively with extraversion, openness, and conscientiousness (the strongest association). These contrasted correlations that problem-solving styles and adaptability show with conscientiousness indicate that they are conceptually different. Moreover, the overlap between these styles, adaptability and personality is only partial.

Adaptability and Intelligence

Adaptive behaviors are usually described as being the result of learned cognitive, practical, and social competencies allowing people to function in everyday life as expected by the cultural group. Emotional disturbance and cognitive disabilities are considered as maladaptive, and the assessment of adaptive functioning is important for diagnosing mental retardation and learning disabilities. Context also impacts adaptive functioning; for example, childhood abuse is linked with the future development of cognitive flexibility and presumably adaptability.

According to Robert Sternberg (1949–), cognitive abilities contribute to adaptive skills and to performance as expected by the social context. General intelligence helps people cope with everyday demands and has thus an important adaptive function. Yet, despite its adaptive function and its correlations with adaptive responses, the association between intelligence and adaptability competences, such as exploratory behaviors or planning skills, is usually small. This confirms that adaptability has to be distinguished from intelligence and adaptive behaviors. An illustration of this phenomenon is that multitasking

abilities predict cognitive skills, such as working memory, but seem to be slightly different from multitasking adaptability, that concerns the ability to respond rapidly to changing task demands. Finally, social intelligence or emotional intelligence is related with adaptability or adaptive abilities in social contexts or tasks.

Adaptability as a Self-Regulation Ability

Adaptability refers to abilities that regulate behavioral and affective expression in order to select adapted behaviors and to feel appropriate emotions associated with low levels of discomfort or cognitive dissonance. Several concepts share common aspects with adaptability, and can be considered to some extent as self-regulation processes. Firstly, three coping skills are traditionally distinguished: Appraisal-focused (understanding the causes), problem-focused (finding a solution), and emotion-focused coping (regulating the affects induced by the difficulty). Secondly, the concept of ego resilience or resilience describes the ability of some people to overcome adverse and stressful situations by reequilibrating their responses to adjust to changing conditions. Then, cognitive flexibility implies a willingness to be flexible and a confidence in the ability to behave effectively; self-confidence can promote a feeling of security allowing flexibility, and can also induce less permeability to external influences. Finally, emotional regulation processes, self-efficacy and outcome expectations are also seen as regulation processes.

Adaptability shares some aspects with all these constructs and contributes along with a clearly structured self-concept to resilience or flexibility. Communication flexibility positively relates to communication adaptability. Moreover, coping flexibility refers to a person's ability to use a diversity of strategies to handle challenges occurring in different circumstances. This coping flexibility is promoted by dialectical thinking capacities and negatively correlates with a need for closure (or an intolerance to uncertainty and ambiguity). Being able to use different coping patterns or strategies, being able to actualize multiple roles, selves, or identities contributes to help individuals adapt to changing circumstances. For example, people with higher coping flexibility are less sensitive to stressful situations and tend to have a lower systolic blood pressure in those situations. Thus, individuals with a wide array of self-regulation abilities probably have fewer difficulties in managing a wide variety of dynamic internal and external constraints.

This regulation is possible because these processes are sensitive to the environment and contribute thus to an adaptive feedback loop. Taking into account information from that loop, activating the most adaptive mechanism, and adjusting one's behavioral expression is likely facilitated by one's self-awareness. The self, the multiple selves, or the self-concept constitutes a meta-competency that manages the activation and allocation of these adaptive resources. Moreover, adaptability, self-efficacy, and outcome expectations promote an anticipation of the implications of one's choices and behaviors. Thus, these processes can help people adopt preventive and protective behaviors. This property of adaptability also contributes to self-directedness and to people's proactivity, referring to anticipatory and change-oriented behaviors with an impact on the environment. Adaptability is therefore not only about people's adaptation to the external constraints but also about adjusting the context to their needs.

Adaptability, Health, and Career Outcomes

Adaptability and Well-Being

Several studies have shown that regulation processes, such as adaptability or self-efficacy, are positively linked with psychological health and well-being. These self-regulation processes are positively related to life satisfaction and positive affect and negatively related to negative affect. At the same time, reciprocal influences between these psychological resources, well-being, and overall quality of life are very likely, as illustrated by the fact that the relationship between adaptability and life satisfaction is partially mediated by hope. Moreover, adaptability has long-term implications for life satisfaction and well-being since it influences affect well-being even one year later. Considering that adaptability is thought to be strongly influenced by circumstances, these long-term effects of adaptability might be explained by positive short-term impacts triggering a virtuous circle between adaptability, adaptation, positive emotions, and well-being.

Adaptability at Work

According to the theory of work adjustment, the P-E fit implies a fit between abilities and requirements on one side, and values and reinforcers on the other side, leading respectively to satisfactoriness and job satisfaction. This adjustment process implies usually an adaptation that can be active, by changing the context, or reactive by adapting to the context. Organizations today are often very dynamic and changing environments require from employees a constant adaptation. The underlying ability to adapt is associated with the capacity to handle work stress, crises, unpredictable work situations, learning new work situations, etc. Adaptability is an important predictor of academic achievements, job engagement, and job performance, especially when this performance occurs in a dynamic situation. For example, the adaptability of telemarketing sales representatives during interactions with clients predicts their sales performance. In the workplace, cognitive adaptability is also known for being negatively linked to unrealistic expectations that in turn are associated with less burnout. Furthermore, adaptability also contributes to people's employability and their ability to gain and maintain employment.

Career Adaptability

In the contemporary world characterized by the emergence of new technologies, globalization, downsizing, or even rightsizing, being adaptable and able to learn have become crucial abilities to plan and self-manage a personal career. The psychosocial construct of *career adaptability* has been developed to describe a set of abilities contributing to people's competence to make appropriate career choices, manage and construct their career, and design their life. Career adaptability includes a set of four abilities: Concern, associated with the ability to plan; control, associated with the ability to make decisions; curiosity, associated with the ability to explore; and confidence, associated with the ability to solve problems. Career adaptability is positively linked with P-E fit, job performance, and employability, and negatively with turnover intention. Thus, organizational retention

strategies should pay particular attention to unsatisfied but adaptable people more at risk of leaving the organization. Of course, individuals do not only use internal resources to cope with their professional environment. Other resources, such as social support, are also very important. However, an adaptable person might have more facilities to take advantage of external resources.

Role of Adaptability for P-E Relationships

The self-regulation process at the core of adaptability implies that it mediates, and/or moderates the behavioral expression of personal dispositions, to adjust this expression to environmental expectations. Moreover, adaptability also mediates the environmental impact on the relationship between dispositions and behaviors. This mediation may constitute one of the pathways of the feedback loop of adaptation. For example, career adaptability is known for partially mediating the relationship between internal dispositions, such as personality or orientations to happiness, and work-related outcomes, such as work engagement or work stress. Similarly, adaptive skills mediate the relationship between values and contextual work-performance. As expected, career adaptability also mediates the impact of external constraints, such as job insecurity or job strain, on work-related behaviors or well-being outcomes, such as job satisfaction, work stress, life satisfaction, or psychological health. Psychological flexibility helps people deal with adverse job conditions, and overwhelming social interactions, but this help is particularly effective when people are not exhausted. Thus, adaptability has an impact on the demands-exhaustion-performance relationship by diminishing the negative impacts of job demands on exhaustion and performance, but these relationships are complex and certainly not all linear. Highly adaptable people also invest more in maintaining an adequate P-E fit. As such, they are proactive in their relation with their environment. Finally, adaptability also helps people choose an environment adapted to their aims and goals, by diversifying their options. Still, even though adaptability is an important regulation process, other processes, such as emotional regulation, self-efficacy, or humor, also contribute to this self-regulation.

Enhancing Adaptability

A secure familial environment and parental behaviors of acceptance and involvement favor the development of children's adaptability. One goal of education is to increase children's ability to cope with novelty, new tasks, and social situations. As such, for a social group or a family, this adaptability implies the ability to change its rules, its way of functioning, and its members' roles in response to new circumstances. Interestingly, some authors consider that being too adaptive, especially for a family, can be potentially problematic due to the lack of structures, but that a lack of adaptability might also be problematic due to the rigidity that it implies. When getting older, the unity of the self, openness to experience, flexibility, and adaptability tends to decrease slowly.

If adaptability seems to evolve during the life-span, it also seems to change quite rapidly due to circumstances. For example, people with slightly higher adaptability have a more

stable employment situation, suggesting that adaptability helps them find more favorable job situations. Yet, unemployed people seem to have higher levels of adaptability, suggesting that people activate their resources and adaptive skills in adverse situations. Similarly, but in an opposite direction, once a career choice is made, career adaptability seems to decrease. Thus, adaptability is a dynamic component of a person varying with circumstances.

One way to help people cope with stressful or changing demands is to stimulate and enhance these regulation or adaptive processes in order to promote an easier adaptation. Several interventions have been developed to increase emotional regulation competences and they have been shown to be very effective. Moreover, adaptability-centered brief-career interventions have proven to increase counselees' employability, job satisfaction, person-organization fit, and career success, as well as to decrease turnover intentions.

In sum, adaptability is an important regulation process allowing people to adjust to and select their environment, and it can be improved by specific psychological interventions.

Aggression, Personality Correlates

Anita Feher

University of Western Ontario

Aggression is defined as any behavior that individuals engage in to purposely cause harm to another unwilling individual. The majority of studies concentrate on the negative implications aggression has for self and others. In its extreme form, where serious harm to another person is intended, aggression is called violence. Despite its negative connotations, aggression was considered beneficial in our evolutionary past, where it helped in protecting territory and offspring. Aggression is a highly complex construct, and has psychological, social, biological, and cultural origins. It appears in various forms (e.g. physical, verbal, and sexual), and across many contexts (e.g. school, workplace, home environment, etc.).

Classifications of Aggression

Aggression can be classified into three separate categories that tap into the reasons individuals had when committing the act of aggression. However, aggressive acts may encompass more than one type. Hostile aggression is usually an unplanned act whose purpose is to cause harm to someone else, and is due to being in a negative emotional state. Instrumental aggression is premeditated behavior where a person commits an act of aggression in order to make some gain. Finally, relational aggression involves behaving with the intention of harming the social relationships of another person (e.g. through gossip).

Aggression can also be classified according to Kenneth Dodge and colleagues' proactive versus reactive aggression. Proactive aggression is pre-planned aggression, oriented toward achieving some goal. Reactive aggression is aggression in reaction to some perceived threat.

Theories of Aggression

Instinct Theory

According to Freud, aggression is instinctual in nature and inevitable. It stems from the innate death instinct he believed was possessed by all humans, which is destructive and aims to end life. This death instinct causes aggressive urges which build up and must be expressed, either outwards toward others or inwards toward the self. When it is expressed outwards, it can be either done in a socially acceptable form (e.g. through play), or through unacceptable means (e.g. fighting).

Another supporter of an instinctual depiction of aggression was Konrad Lorenz, who said that humans (and other animals) possess a fighting instinct. This aggressive energy builds up continuously, and must be relieved, or else it will release even when an appropriate stimulus isn't available.

Social Learning Theory

Developed by Albert Bandura and colleagues, this theory proposes that aggression is learned from observing others committing aggressive acts, as well as seeing whether that behavior gets punished or rewarded. One famous experiment illustrating this theory was the Bobo doll experiment (Bandura, Ross, & Ross, 1961). In this experiment, children who observed adults performing aggressive actions against a Bobo doll (e.g. hitting with a mallet) were more likely to imitate such behaviors and overall behave more aggressively, in comparison to groups that had not observed the aggressive adult.

Script Theory

Scripts can be defined as sets of knowledge that define a situation, and inform people about what behaviors to use in that given situation. This theory describes how aggressive scripts we learn, for example from the mass media, can influence our aggressive behaviors in future interactions (see Huesmann, 1986). Aggressive scripts are learned over time and can become easily accessible, making aggressive responding more likely in situations.

Frustration-Aggression Hypothesis

This theory claims that frustration as a result of having one's goals obstructed leads to aggressive behavior, and furthermore claims that aggression is only caused by frustration (see Dollard, Doob, Miller, Mowrer, & Sears, 1939). While frustration is sometimes the cause of aggression, future studies disproved the notion that it is always the cause. One concept that fits with this theory is displaced aggression, which is when aggression cannot be directed at the original source of provocation (the source of frustration), and is thus directed at a non-related and often innocent target.

The theory was later revised by Berkowitz, who claimed that negative affect caused by frustration, or other sources, creates a state of readiness to behave aggressively, and also

that aggressive behavior will manifest in response to aggressive cues in the environment associated with aggression.

Excitation Transfer Theory

According to this theory, physiological arousal (e.g. from exercise) when in concurrence with an anger-inducing experience can cause people to misattribute their arousal, and become even angrier and more aggressive (see Zillmann, Katcher, & Milavsky, 1972).

Cognitive Neoassociation Theory

This theory views aggression as a result of negative affect, and of spreading activation of thoughts, memories, and reactions related to aggression (see Berkowitz, 1990). Negative events are thought to cause negative affect, which in turn activates flight (and feelings of fear) or fight (and feelings of anger/aggression) related cognitive schemas, as well as physiological and motor reactions. Stimuli associated with the negative event can become associated with aggression-related cognitions. Berkowitz and colleagues also state that situational cues and stimuli relating to aggression (e.g. weapons) have the potential to elicit aggressive responses.

General Aggression Model

This model developed by Craig Anderson and colleagues integrates many of the aforementioned theories by conceptualizing aggression as a series of connected processes (see Anderson & Bushman, 2002). The model begins with person-centered and situational variables as inputs. These cause aggression-related thoughts, feelings, and physiological arousal to occur. Finally, these lead to appraisal and decisional processes that determine action and social outcomes.

Other Influences on Aggression

Biological

There are a number of biological influences that have been suggested to affect aggression levels. Dysfunction in the activity of brain regions, including the prefrontal cortex, amygdala, and anterior cingulate cortex, is suggested to cause increased aggressive tendencies. Hormonal influences in the form of testosterone are suggested to have a positive and reciprocal relationship with aggression. The neurotransmitter serotonin also has an impact on aggression levels, with lower levels of serotonin being linked to aggressive behaviors. Ingested substances like alcohol are also linked to increases in aggression.

Cultural

Different cultures have different norms with regard to the acceptability and frequency of aggression. For example, societies with higher gender inequality norms tend to have more incidents of violence against women. An experiment by Cohen, Nisbett, Bowdle, and

Schwarz (1996) showed that when comparing men from Northern versus Southern USA, men from the South are more likely to demonstrate a readiness for aggression and aggressive behavior after they were insulted, due to their "culture of honor."

Personality Characteristics and Aggression

There are clear individual differences in the frequency with which people behave aggressively. These individual differences refer to personality characteristics that cause certain individuals to become higher or lower in aggression compared to others.

Trait Aggression

Trait aggression considers aggression a personality trait instead of just a situational response. People who score high on trait aggression tend to habitually respond to situations in a more aggressive manner. Buss and Perry (1992) developed the Aggression Questionnaire (AQ) to measure trait aggression. The AQ is composed of four subtraits relating to trait aggression: physical aggression, verbal aggression, anger, and hostility. Individuals who score higher on this scale are considered to be higher in trait aggression.

Five Factor Model of Personality

The personality traits openness, conscientiousness, extraversion, agreeableness and neuroticism have demonstrated relationships with aggression. This fits with the general aggression model, which states that personality traits are one of the factors that influence aggression. Agreeableness has been shown to have the strongest (negative) relationship with aggression out of the five personality factors. With regard to the other personality traits, conscientiousness generally has a negative, and neuroticism a positive association with aggression. Findings in the research literature show mixed results for openness and extraversion.

Narcissism

Narcissism is defined as having high regard for oneself and a sense of superiority. Studies have demonstrated that narcissistic individuals, whose self-regard is high but unstable, become aggressive if they experience criticism, and thus have their ego threatened (i.e. they experience threatened egotism). Acts of aggression are committed (often against the person who criticized them) in order to protect their self-image as well as to re-establish dominance.

Rejection Sensitivity

Humans have an innate need to belong socially, and those who are unable to fulfill that need often react in an unproductive, antisocial manner (e.g. aggressively). Some individuals are especially sensitive to interpersonal rejection, and possess a "cognitive-affective

processing disposition" called rejection sensitivity (RS; see Downey & Feldman, 1996). Individuals high on RS anxiously expect rejection from other people, as well as having a tendency to over-react to perceived rejection. Studies have demonstrated that those with high RS often react aggressively when they feel like they were rejected, and can do so even when low RS do not react to that situation aggressively. However, high RS individuals are not more aggressive in general; their aggression is incited by a defensive response to a perceived rejection episode. High RS has negative interpersonal consequences, for example high RS of men invested in their romantic relationships can serve as a predictor of physical aggression against intimate partners.

Consequences of Aggression

The interpersonal and intrapersonal consequences of aggressive behavior in studies are predominantly negative, and extend into many domains of life. For example, when considering intrapersonal consequences, studies have demonstrated an association between aggression and having lower life satisfaction, having a higher risk of heart-related health problems, and being more likely to engage in risky health behaviors.

Interpersonal consequences of aggression affect both the perpetrator and the target of aggressive behavior. For example, being the target of aggression is more likely to make that person aggressive. Victims of domestic violence have higher risks of developing physical and mental health complications, parental rejection and/or abuse has been linked to increased aggressive behaviors in children. Children who act aggressively are more likely to drop out of school, and aggression in the workplace leads to decreased job performance.

Future Directions

While the topic of aggression has been vastly studied across multiple domains, there are nevertheless still many avenues that require further exploration. For example, what combinations of various individual difference variables influence aggression is one possible area of future research. While interventions for aggression do exist already, grouping different interventions to increase their benefits or targeting interventions to deal with each type of aggression would be of great value. Interventions to decrease aggression in various settings, across age groups, and in different cultures is also an area that is still ripe for further research.

Altruism

Melissa Yue and Emma A. Climie

Werklund School of Education, University of Calgary

Altruism refers to the act of helping or benefiting others on an individual or societal level and is often synonymous with being selfless or prosocial. More specifically, altruism occurs when an individual voluntarily assists another despite the cost of time, money, or other resources required to help. Altruistic behaviors include sharing, donating, co-operating, or volunteering. For example, a man who goes into a burning house to save a child would be considered to have acted altruistically; he has performed a positive action to benefit others or society with no expectation of personal reward or benefit. The decision to help someone varies between individuals and situations. Individuals must see the need to help and feel they have the proper resources to give adequate assistance. Even when a need is identified and the resources are available, an individual's personality or beliefs can also influence whether a person will commit to helping.

However, some altruistic behaviors may not appear to be helpful at first. For example, Murielle decides not to help her friend, Albert, complete his homework on time because she wants him to learn the material himself and to prioritize his work next time. Albert might feel that Murielle is being mean; however, Murielle has his best interest at heart. Alternatively, an altruistic individual can punish someone who is behaving poorly in order to correct the behavior. These altruistic punishments serve as a way to redirect undesirable, selfish behaviors that deviate from a society's standard of fairness as well as to aid the victim (Fehr & Fischbacher, 2003).

Theoretical Views

Different perspectives on altruism have emerged in biology, anthropology, and psychology. The biological perspective focuses on the costs and benefits associated with helping another. In the animal kingdom, altruistic behaviors are largely limited within social groups that are genetically related to each other. Biologists note that certain species of animals will decrease their chance of surviving and reproducing only if their sacrifice can

increase the chance of a relative's ability to survive and reproduce, known as kin selection. Humans appear to be a rare exception to helping both related and unrelated individuals, as they often co-operate with others to achieve a common goal. Consequently, humans engage in altruism at a much higher frequency than animals. Anthropologists aim to understand how the helping behaviors evolved in humans despite the often high cost associated with helping others. For instance, if Dianna helps Andrew in one of his class projects instead of focusing on her own studies, Dianna will be increasing Andrew's success while decreasing her own. At a later time, Andrew returns the favor and helps Dianna study for her finals. This phenomenon, referred to as reciprocal altruism, demonstrates the pattern of turn-taking to reinforce future helping behaviors and may be one explanation for why humans engage in altruistic behaviors.

The field of social psychology has played the largest role in furthering the understanding of the motives behind why an individual would want to co-operate or help in a situation, including what factors impact one's decision to help. Two predominant theories have been put forth: social exchange theory and Batson's prosocial motivation model. Social exchange theory notes that prosocial behaviors will only occur when the benefits outweigh the cost associated with helping. Although relatively simplistic, four motivations for prosocial behaviors have been identified. First, helping can occur when individuals believe that it will benefit themselves in the long run (e.g. Nathan helped May now because he knew she would help him later). Second, helping can occur to truly benefit another with no ulterior motives (e.g. the elderly stranger needed help crossing the road and Lee went to help her). Third, when helping benefits a group (e.g. Christine took a penalty for the team). Finally, individuals may be motivated by their value system (e.g. I will help because it is the right thing to do). However, there is no consensus in the research literature. Some argue that no act is truly unselfish, while others argue that there are particular situations where completely selfless sacrifices are made with no ulterior motives. Regardless, prosocial behaviors are essential to the survival of the human race and the development of successful societies.

Development of Altruism

Learning to help others requires the development of several social skills. A person must be able to identify the intention of another's action through their body language or emotions. At the same time, the potential helper must be able to assess the situation and determine that the other person is in need of help.

One of the first skills children develop before engaging in altruistic behaviors is the ability to understand that another person's feelings and intentions may differ from their own. Prosocial behaviors begin to appear more frequently after the age of one year, yet children begin to understand other's minds around the age of two years. There is debate as to whether toddlers help because they genuinely see a need and want to help, or if they simply want to participate in an interesting task. How a child gives assistance changes rapidly after his or her first year of life. For instance, young children (12–14 months) will help an adult retrieve an object that is just out of the adult's reach. In this situation, a child is responding to an unfinished goal and is able to understand the physical intention of the

adult. However, children are generally not able to assist an emotional distress until they are older (18–24 months). With age, children's self-awareness is more developed and they are better able to understand the internal emotions of others.

By the age of three years, children are able to observe how an adult treats another adult and, based on their observations, children will decide whether or not to help. If a man treats a woman well by helping her, then children are more likely to help the man in a later task. Subsequently, if the man hinders the woman, children are more likely to withhold help from the man later. Therefore, children are selective in who they help and can understand the social value of helping versus harming. By choosing to not help, children demonstrate a form of altruistic punishment where they actively withhold their assistance (Vaish, Carpenter, & Tomasello, 2010).

The difficulty in studying altruism in children and adults is identifying ways to tap into an individual's motivations, as motivations can only be known if they are explicitly reported. Obviously, this challenge is amplified in children because their verbal skills may be unable to articulate their internal thought process. In addition, researchers also have to consider how a child is exposed to the social world. Socialization introduces new motivations such as social acceptance, appearing socially desirable by a certain group, or hoping future help would be offered in return. Because social desirability affects the reporting accuracy of motivations, researchers often question the true meaning behind someone's altruistic behavior.

Impact on Individuals

Regardless of a person's motive, there are many benefits to an individual for acting in prosocial ways. Several studies have looked at the benefits to volunteering. When people volunteer, they perceive their lives as being more satisfactory and fulfilling. In some cases, those who have experienced a past and personal hurt or disappointment often go on to help those who may be currently experiencing similar problems. A key benefit to altruism is that helpers are exposed to more social relationships and hence develop stronger social support systems.

A potential benefit, known as the helper principle, describes a mentality that helpers have regarding their own understanding of why they are helping. When assisting others, a persuasive thought crosses a helper's mind that says "Life must not be so bad if I can afford to help others" (Melkman, Mor-Salwo, Mangold, Zeller, & Benbenishty, 2015). In addition, helping instills a sense of empowerment or reassurance that an individual is making a difference. This attitude can serve as a protective factor against mental health illnesses such as depression. Helping at a younger age also appears to increase the chance of other prosocial behaviors into adulthood and healthier mental sets throughout life.

Measures of Altruism

Altruism is a challenging construct to measure. Research in altruism often requires the participant to demonstrate prosocial behaviors in a particular situation. Rushton, Chrisjohn, and Fekken (1981) developed a 20-item questionnaire to assess a person's altruistic behaviors. The

Self-Reported Altruism Scale requires selection of one out of five frequency responses per item. Some examples of the items include "I have given money to charity" and "I have donated blood." The rater replies on a scale of never, once, more than once, often and very often, with higher scores indicating greater levels of altruism.

Encouraging Altruistic Tendencies

With all the benefits that altruistic behaviors provide, researchers have begun to investigate how to increase prosocial behaviors. One method involves implicitly suggesting that helping behaviors are highly desirable and positive. Because most people generally think of themselves as good, they will adjust their behavior to gain further approval. If a person happens to be acting in a selfish manner, indirectly bringing awareness to the desirability of selflessness may get the selfish individual to reassess their own actions.

As one evidence-based program aimed at increasing altruistic tendencies, Ramia (2005) found that a mandatory learning course with a service-based internship encourages altruism in youth. The program required attendance at conferences as well as publishing reflections in an online discussion group regarding their internship experience. Using the Self-Report Altruism Scale, each participant's altruistic behaviors were assessed before the course began, at the end of the course and one year after the course completion. The results indicated that the program had a positive impact on altruism even after a year had passed and that increasing altruism in others is possible.

Alexithymia

Caitlin J. Spencer[1] and Emily N. Boughner[2]

[1] *Western University, Ontario, Canada*
[2] *University of Regina, Saskatchewan, Canada*

Conceptualization and Measurement

Alexithymia, literally translated as "no words for feelings," is a personality trait characterized by deficits in specific cognitive and affective functions. Individuals high in alexithymia experience confusion when attempting to identify their emotions and have difficulty describing their feelings to others. Though alexithymic individuals are thought to experience emotions, they have difficulty identifying their sources or linking them to concrete thoughts. If asked to describe their feelings, they frequently express uncertainty (e.g. I'm not sure), use vague descriptors (e.g. I feel upset), or opt for descriptions of physical complaints (e.g. my stomach hurts). When recalling or experiencing meaningful personal events, those high in alexithymia often exhibit muted facial expressions and/or a discongruence between behaviorally observable and self-reported emotionality.

Although alexithymia refers to difficulties in understanding one's own emotions, it has also been linked to the misinterpretation of emotions in others. Others' facial expressions (e.g. fear, sadness, and anger) are more difficult to identify, and there is often a delay in noticing changes in those expressions. This frequently results in lower empathic capabilities and a greater indifference regarding interpersonal relationships. Individuals high in alexithymia tend to have smaller circles of close friends and a diminished social support system.

Alexithymia is also marked by an externally-bound style of thinking. This cognitive style includes behaving and making decisions based on rules and expectations of others rather than one's own desires, thoughts, or personal values. Alexithymic individuals often mirror others in their relationships and react as they believe is expected and appropriate instead of based on their own sentiments. Externally-bound thinking is also associated with a reduced capacity for creativity and imagination. Fantasies are scarce and dreams, if they are recalled, are frequently dull in content.

The first cases of alexithymia were measured through clinical interviews and case studies dating back to the late 1940s. Clinicians observed a decreased capability for verbal expression of emotions in patients suffering from post-traumatic stresses, substance abuse, and other psychosomatic conditions. While early attempts to measure alexithymia tended to dichotomize the trait into individuals with and without it, more recent research has identified it as a dimensional construct. Individuals are now considered to be either high or low in alexithymia and several self-report scales have been developed to assess the trait in both clinical and non-clinical populations.

The most often used survey of alexithymia is the Toronto Alexithymia Scale (TAS-20; Bagby, Parker, & Taylor, 1994), whose items measure three separate factors: difficulty identifying feelings, difficulty describing feelings, and externally-oriented thinking. Another popular scale is the Bermond-Vorst Alexithymia Questionnaire (BVAQ; Vorst & Bermond, 2001) which contains five factors: identifying, verbalizing, analyzing, fantasizing, and emotionalizing. The first three are often categorized into a larger cognitive factor and the latter two into an affective factor.

Etiology

Genetic, neurological, and environmental factors are all implicated in alexithymic traits. About 30–33% of the variation in alexithymia scores appears to be due to genetics. Key brain regions involved in the processing of emotional stimuli are also associated with alexithymia, including the anterior cingulate cortex and the medial prefrontal cortex. Victims of traumatic brain injury frequently exhibit alexithymia characteristics, further lending support to a partial neurobiological origin.

Shared experiences between family members have little effect on individual differences in alexithymia characteristics. Rather, unshared or unique experiences explain 50–60% of variation in alexithymia traits. Children who have suffered trauma, interrupting their natural emotional development, are more at risk for developing alexithymia. This trauma can be of a physical nature, although history of emotional abuse correlates strongest with alexithymia. Emotional abuse or neglect is especially potent when coming from the child's parents. Neglectful parenting styles can lead to children developing insecure attachment relationships. A lack of nurturing, perceived neglect, overprotection, and intrusive parenting can lead to a controlling relationship that lacks affection. This emotional neglect can disrupt the normal childhood development of emotion regulation, including the ability to identify and label emotions in self and others. Thus, alexithymia is more likely to develop in persons who have experienced psychological trauma in early childhood, particularly if it leads to post-traumatic stress disorder (PTSD).

Associated Illnesses

Typically, people with alexithymia are unable to identify the emotional causes of their physical symptoms, and therefore may assume that their symptoms are due to a physical illness. Psychosomatic disorders are those which both the body and mind contribute to

the manifestation of a physical illness, but individuals with alexithymia have difficulty in identifying the mental or emotional component. Owing to this, higher levels of alexithymia may play a role in the development of physical diseases such as hypertension, peptic ulcers, and chronic pain issues.

Although first identified in people with psychosomatic disorders, alexithymia has also been found to play a significant role in other clinical populations. It has been linked to several psychiatric disorders and is often used as a predictor of their treatment outcomes. Alexithymic characteristics are frequently identified in persons with substance abuse, post-traumatic stress, autism spectrum, anorexia nervosa, anxiety, and depressive disorders.

Related Psychological Concepts

Alexithymia has often been studied alongside psychological defense mechanisms or repressive-defensive coping styles. The latter are typically considered separate but related constructs wherein the mind is defending itself by decreasing emotional involvement. Both alexithymia and defense mechanisms include psychological withdrawal, or a person psychologically distancing themselves from thoughts, people, or situations. As well, both alexithymia and defense mechanisms include processes of inhibition, where thoughts and emotions are not actively expressed. However, individuals employing a repressive-defensive coping style often score low in alexithymia. Repressors may deny or avoid their experience of emotions, whereas alexithymic individuals acknowledge their feelings, but have difficulty elaborating or expressing them.

Anhedonia is also conceptually related to alexithymia. While alexithymia is defined as the inability to identify and describe emotions, anhedonia is the inability to derive pleasure from usually enjoyable activities. Both alexithymia and anhedonia are concepts that are frequently characteristic of psychiatric disorders, such as post-traumatic stress or anorexia nervosa.

Emotional numbing, a symptom cluster within PTSD, also shares conceptual similarities to alexithymia. Emotional numbing is often described as an inability to emotionally connect with others, and an affected person may not feel fully in the present. Emotionally numb individuals may have difficulties with creating meaningful emotional ties with people due to reduced affect or emotional feelings.

Alexithymia has been found to be negatively related to the concepts of psychological mindedness and emotional intelligence. Alexithymia can be considered the opposite of psychological mindedness, defined as a person's ability to examine their own emotions, thoughts, and feelings, as well as the ability to see the underlying meanings of events and emotions. Those who display alexithymia often score low on psychological mindedness, indicating a difficulty in recognizing their own emotions. Those who score high on alexithymia and low on psychological mindedness have extreme difficulty responding to treatment.

Emotional intelligence (EI) is considered to be the ability to perceive, understand and act upon one's own emotions, as well as those of others. Alexithymia correlates with a low capacity for empathy, and people high in alexithymia usually score low in both self-report and ability tests of EI.

Treatment or Reduction of Alexithymia

Alexithymia is considered a relatively stable trait, making it particularly resistant to efforts to reduce it. Treatment of comorbid disorders such as depression has had some success in reducing alexithymia levels, however, it is important to take the type of treatment into consideration. Cognitive behavioral therapy has been shown to be effective for persons high in alexithymia, whereas reflective psychotherapies which demand an insight into the patient's emotions are thought to be less effective.

Historically, the treatment of alexithymia when targeted individually has involved a long and slow process, taking the form of a psychoeducation about emotions. The clinician explains to the alexithymic patient how their emotions can manifest as physical symptoms or behavioral expressions, and teaches them to correctly identify them. Efforts are made to strengthen the patient's ability to connect bodily sensations with images and words. For instance, a fluttering feeling in the stomach may be explained as a physical reaction to anticipation or anxiety. Imaginative processes are also frequently encouraged as the clinician helps the patient explore fantasy and the meaning of dreams, broadening the patient's narrow tendency toward an externally-oriented thinking style.

Role playing may also be used to provide guidance concerning non-verbal communication. When treated in groups, patients have more opportunities to engage in interpersonal situations and practice identifying the emotions of others.

Future Directions and Studies

Most research concerning alexithymia is cross-sectional and relies on self-report questionnaires. Newer methods to measure alexithymia, such as observer reports and structured interviews, are increasingly being employed to provide a multi-method approach to studying alexithymia. There are advances still to be made into the etiology of alexithymia, particularly the influence of early attachment styles and the interruption of emotional development, and the most effective means of treating persons suffering from psychological disorders with which it is associated.

Androgyny, Expression of

Emily R. Bunnett

Swinburne University of Technology

The psychological construct of androgyny has gained much attention over the past four decades following an important advancement in sex-trait theories concerning the structure of masculinity and femininity. That is, the adaptation of a sex-trait model comprising two orthogonal dimensions, over the original conceptualization purporting masculinity and femininity as bipolar opposites of a single continuum, enabled androgynous types to be accounted for. Through removing the restrictions proposed by a mutually exclusive singular dimension, it allowed theorists such as Bem and colleagues (e.g., 1977) to operationalize sex-traits as coexisting dimensions that may be present in the traditionally disproportionate manner reflecting gender stereotypes or in equally high or low levels within a single individual. Specifically, people scoring high on one dimension but not the other are considered sex-typed, whilst those scoring high and low on both are denoted androgynous and undifferentiated, respectively.

Bem and Lewis (1975) operationalized androgyny as the equal endorsement of socially desirable masculine and feminine characteristics. Therefore, androgyny is commonly measured by presenting participants with a series of socially desirable characteristics relating to masculinity and femininity and asking them to endorse all which they believe themselves as possessing. The Bem Sex Role-Inventory (BSRI) was the pioneering measure of psychological androgyny formulated using this form of rating system. Participants' relative standings on the masculinity and femininity scales (termed instrumental-expressive by Bem) are then calculated to formulate a trait description of high-low for masculine, low-high for feminine, high-high for androgynous and low-low for undifferentiated. Therefore, Bem purported that androgyny presented the new standard for good mental health, enabling individuals to be both instrumental and expressive, assertive and yielding, dominant and nurturing and to adapt a situationally flexible interpersonal demeanor, ensuring that their behavioral responses and expressiveness are contextually appropriate. The greater behavioral flexibility of androgynous individuals is said to reflect their possession of both feminine and masculine qualities, in addition to the fact that they do not rely on cognitive gender schemata to organize their behaviors, attitudes, and perceptions. Androgynous

individuals are thus said to not internalize the societal pressures placed on adherence to the traditional gender roles, whereas sex-typed individuals tend to restrict their behavior according to the bounds outlined by those considered stereotypically appropriate for their gender. It has therefore been suggested that androgynous persons see gender differently from sex-typed individuals.

Nevertheless, Bem's scale and theory were later criticized for lacking the inclusion of negative characteristics in the formation of the BSRI scales and its sole focus on interpersonal relationships/adjectives, failing to include androgynous acts, behaviors and attitudes, and intellectual, material and temperamental adjectives (Lefkowitz & Zeldow, 2006). Therefore, the operationalized definition adopted combines that derivative of development psychology and that of social psychology. Specifically, androgyny may be defined as an individual who possesses both the dominant, instrumental, tough, decisive and intellectual characteristics typically deemed male or masculine in nature and the nurturing, expressive, delicate and submissive characteristics stereotypical of females and feminine types, that is, having the temperament, advantages and strengths of both, alongside being able to act in situationally appropriate ways due to their flexible, integrated disposition. Moreover, these limitations of earlier studies suggest that alternative forms of sex-trait measurement should be utilized, such as the use of other individuals to rate participants' relative standing on both positive and negative characteristics, behaviors and attitudes commonly considered representative of either masculinity or femininity and not the other (Lefkowitz & Zeldow, 2006).

Personality Correlates of Androgyny

As aforementioned, androgynous individuals are considered to comprise an equally high share of characteristics traditionally considered masculine and feminine. Therefore, the following depictions of these two sex-traits may be considered coexistent within the androgynous type. Nevertheless, androgynous individuals have also been found to display several characteristics and behavioral traits that are not indicative of either masculinity or femininity. Masculine females and males generally possess strong independent and decisive traits including: dominance, leadership qualities, aggression, social ascendency, assertiveness, strength, autonomy, ambition, independence, self-reliance, intellectual ascendency, agentic, willingness to take a stand, athleticism, competitiveness, individualism, risk seeking tendencies and forceful. In comparison, feminine females and males tend to display softer and more dependent characteristics, such as being tender, submissive, compassionate, nurturing, warm, sympathetic, sensitive, affectionate, expressive, agreeable, understanding, gullible, introverted, shy, communal and self-subordinating.

In addition to exhibiting an equally high proportion of the above characteristics, androgynous individuals also tend to display more social poise, intellect, social competence, and creativity. Conversely, undifferentiated individuals tend to score low on masculine and feminine traits and display more negative characteristics, such as, being unassured, self-doubting and aimless. A clear comparison between these two groups is the fact that high-high (androgynous) individuals commonly rate themselves as exhibiting more positive

characteristics, while low-lows (undifferentiated) frequently attribute negative traits to themselves. Further differentiations are apparent when these groups are compared on several autobiographical variables, such as evidence that androgynous individuals tend to report fewer childhood illnesses, more frequent dating, and greater scholastic achievements than undifferentiated individuals.

Moreover, Wiggins and Holzmuller (1978) found androgynous females to attribute aggression, bossiness, daintiness, extraversion, gullibility, over-talkativeness, perkiness, naivety, uncalculatingness, geniality, vocality, bluntness, vivaciousness, fickleness, emotionality, animatedness, directness, excitability, frightenability, open-heartedness, peppiness, solicitousness and rambunctiousness significantly more often than androgynous males. Similarly, androgynous males tended to rate the characteristic features of quietness, shyness, antisociality, bashfulness, lacking emotion, silence, soft-spokeness, calmness, lack of feeling, hard-heartedness, toughness, indirectness, meekness, lack of aggression, passivity, reservedness, lack of dramaticality, calculatingness, arrogance, lack of excitability, lack of romance, and taciturnity significantly more than androgynous females did.

Behavioral Expression, Activation and Inhibition

Expressivity is said to be more strongly related to femininity than masculinity, especially for women, but the characteristics that comprise femininity do not necessarily correlate with expressivity. Furthermore, androgyny is purported as reflecting the more comprehensive concept of interpersonal flexibility. The fact that androgynous participants tend to more willingly, openly, actively and happily partake in gender atypical activities and feel no sense of shame or embarrassment after having done so supports this notion. Taken together, it is conceivable that androgynous individuals may be considered the most behaviorally expressive and less inhibited in their range of situationally diverse behaviors. Indeed, previous research has found that androgynous individuals tend to be the most expressive, followed by feminine and finally by masculine individuals. Specifically, androgynous people report being more dispositionally expressive and more expressive of their love, happiness and sadness than sex-typed individuals. Moreover, others tend to rate them as more facially expressive when depicting sadness, fear, anger, disgust and happiness than masculine and feminine types (Kring & Gordon, 1998).

The greater levels of expressivity shown and reported by androgynous individuals may be associated with findings indicating that they tend to be more extraverted than both sex-typed and undifferentiated individuals, the latter of whom commonly score highest on ratings of introversion. Similarly, androgynous persons are able to adapt their behavior according to situational demands, not feeling any pressure to modify their behavior according to gender stereotypes. Therefore, being androgynous may enable one to participate in varied contexts appropriately and hence actively (i.e., be more expressive), while also providing the skills required to inhibit alternative behaviors that would be considered inappropriate in the circumstance at hand, and reinforcing their continued behavioral expressiveness in a variety of contexts. Androgyny has thus often been considered the most adaptive and beneficial sex-trait.

Advantages of Androgyny

Androgyny was first proposed to be the most adaptive and effective sex-trait by Bem and Lewis (1975) in their series of work indicating that it provided individuals with a behavioral repertoire consisting of both feminine and masculine traits, thereby giving androgynous individuals a level of behavioral flexibility unknown to the sex-typed individual. Specifically, androgynous individuals are not restricted by the gender stereotypes held as the acceptable social norms, whereas sex-typed individuals are bound by their unwillingness or inability to perform gender reversed acts. That is, masculine and feminine persons commonly gauge their behavior according to gender roles rather than what a given circumstance calls for, while androgynous individuals consider the situation and adapt their behavior accordingly. This behavioral flexibility was said to result in greater reinforcement of androgynous individuals' behaviors as they were more frequently considered appropriate in the given circumstance. Moreover, greater social reinforcement was considered imperative in boosting one's self-esteem and confidence, alongside presenting other interpersonal benefits (e.g. being more mature in the acts in and judgments of social situations).

However, contrary to such propositions, rating oneself as possessing more masculine than feminine features was more consistently associated with greater benefits for self-esteem than androgyny. Nevertheless, prior to the work of Lefkowitz and Zeldow (2006) the research on sex-traits had relied solely on self-reports, with results arising from alternative methodological procedures providing strong evidence for the potential benefits that androgyny holds over masculine, feminine, and undifferentiated types. These findings suggest that while masculine individuals tend to rate themselves higher on measures of self-esteem, androgynous individuals actually possess greater self-esteem.

Similarly, clinical judgments indicate that despite some findings of higher self-reported psychological well-being for masculine types, androgynous individuals are commonly the most psychologically healthy, present the least amount of psychopathology (e.g. less neuroticism, anxiety, and depression) and adopt more positive and adaptive coping mechanisms. Androgynous children and adults also tend to exhibit the greatest physical health and fitness, in general. Furthermore, androgynous individuals tend to display greater social competence, satisfaction with life, self-regard, self-acceptance, confidence, synergy, inner support, time competence, motivation to achieve, marital satisfaction, parental success, creativity, optimism, subjective well-being, sense of security, social adaptation and capacity to adapt and accept oneself as they change across contexts and time. Finally, androgynous individuals tend to be rated by others as the most liked, adjusted, and sexually attractive. Nonetheless, it is important to note that most of the previous findings have been centered on correlational studies and analyses of variance, hence causation cannot be implied. That is, there is always a certain degree of extraneous variation, whether it be from person-centered differences or variables excluded from the study alongside variations across cohorts, cultures, situations and testing procedures, all of which require consideration. However, the results do suggest that, on average, androgyny is more frequently associated with better health, overall social proficiency, acceptance, adaptability and appraisal, greater psychological well-being, interpersonal maturity and a personality profile that they willingly temper to the demands, needs, and wants of the situation and people involved, freedom to be who they want and what is most appropriate in the situation they either actively choose or find themselves in.

Moreover, the findings provide evidence that androgyny has distinct advantages over masculine, feminine, and undifferentiated individuals, in both Western and non-Western cultures as they tend to exhibit more free willing characters which result in greater health benefits and social outcomes. Nonetheless, androgynous individuals may be more varied in terms of their general profile and hence an appropriate standard or comparison must be ascertained when determining the relative benefits they may hold against these counterparts when it comes to a specific target population. Likewise, it is important to note that what constitutes masculinity and femininity and hence androgyny varies across cultures according to what behaviors and characteristics are considered desirable, natural, and stereotypical of each gender. The beneficence of androgyny over other sex types may, therefore, also depend on the degree to which strict adherence to gender rules (or social norms) is viewed as important in the society.

University of Western Ontario

Conceptualizing Anger

Anger has traditionally been defined as a core emotion that results from the obstruction of a goal or from a provocation such as a verbal or physical attack. Darwin described anger as an action orientation to counteract the obstacle. Anger as a research topic remains of highest importance to this day because it often leads to negative consequences such as aggression and violence. Many social situations can lead to anger, especially when a provocation is perceived by the offended person as intentional. As Aaron Beck (1976) illustrates in his book on the cognitive behavioral treatment of emotional disorders, encroaching on someone's rights, verbal attacks in the form of criticism, coercion, rejection, deprivation, opposition, exclusion, annoyances, rude or disrespectful behavior, and violations of rules are typical triggers of anger. At the physiological level, anger activates the sympathetic nervous system and thus mobilizes energy, tenses the muscles, and increases the heart rate, blood pressure, levels of adrenaline and noradrenaline. With this surge of energy, the angry person can feel confident, strong, alert, determined, courageous, and impulsive. The feeling of anger may also include descriptions such as hot sensations, a jolt of energy, and a pulsating heart. Thoughts are focused on themes of injustice, and motives are dominated by expressions of grievances and restoration of justice. The angered person may respond with specific verbal or physical expressions or may refrain from any action. One of the defining characteristics of core emotions such as anger is their specific associated facial expressions usually involving specific facial muscles. For anger, the typical facial features are lowered eye brows, thinned lips, a flared nose, and raised cheekbones.

Distinctions Between Hostility, Aggression, and Anger

Contemporary theories of affect tend to view anger and other emotions as involving complex associations between affective states, cognition, motivation, and behavior. Although the concept of anger has sometimes been used interchangeably with hostility

and aggression, meaningful conceptual differences and theoretical associations do indeed exist between these three constructs.

Hostility vs. *Anger* Although anger includes thoughts or appraisals about the external environment, particularly focusing on the meaning or intentionality in social interactions, hostility tends to refer only to the thoughts. In the *Aggression Questionnaire* developed by Buss and Perry (1992), the Hostility scale includes items that refer to thoughts of getting a raw deal out of life, whereas anger refers to behaviors such as letting irritation show. Hostile thoughts have themes of cynicism, denigration, jealousy, mistrust, resentment, suspicion, and unfairness. Hostility may exist on its own as a stream of thoughts preceding a full anger response or take the form of a more ongoing rumination. Hostile thoughts often arise in response to the perception that another person intended to do harm, and some people will react more strongly than others to specific types of social threat such as general injustices or situations involving threat to self-esteem. Hostile thoughts can take the form of rumination, leaving a person constantly primed to experience anger in response to minor triggers.

Aggression vs. *anger*. Aggression is defined as a behavior directed with the intent to harm someone. In distinguishing between anger and aggression, it is important to highlight two general categories of aggression: reactive-angry aggression and instrumental aggression. In reactive-angry aggression, a person has experienced some kind of provocation and reacts with an aggressive behavior. The reaction typically involves anger, but it is the action that defines aggression. Where the distinction between anger and reactive-angry aggression becomes a bit obscure is in examples of behavioral expressions of grievances that may or may not include intent to harm. In instrumental aggression, the aggressor is not necessarily provoked or angry. Reactive acts of aggression result from triggers or provocation whereas instrumental acts tend to be premeditated and do not necessarily involve angry reactions.

State and Trait Anger

The experience of anger can usually be demarcated within the stream of affect and defined as a state. Emotional experiences such as anger are common experiences that come and go. When the stream of affect is not dominated by strong emotions, people are more likely to describe how they feel in terms of their current mood. Such mood descriptions can include less intense negative affect in milder forms of anger such as irritations or annoyances. Some people are prone to experience anger much more intensely, more frequently, and in many more situations than other people who seem to remain calm even when provoked. It is therefore meaningful that much research in anger has investigated the role of dispositional factors.

Psychological traits refer to stable patterns in thought, behavior or affect across situations and over extended periods of time, typically in years. A person who experiences frequent and intense states of anger in various situations and shows a stable pattern of anger over time would be inferred to have high trait anger. The stable pattern may be expressed at the level of cognition, the intensity of affect, and the behavioral reaction. The cognitive dimension of trait anger may involve a hostile-attribution bias, characterized by a tendency to view hostility

where it does not really exist. The affective component may include a strong physiological reaction, not unlike the strong signal of a siren in contrast to a much weaker car horn. The behavioral reaction of the high trait individual would appear as regularly explosive, exaggerated, and usually perceived as uncalled for by observers.

The underlying causal factors of trait anger can be studied at several biological and psychological levels. Molecular genetics have focused on identifying candidate genes, while behavioral genetics have investigated the proportion of variance in traits attributable to heredity. Other studies have investigated the influences of hormonal and specific brain structures. Early maladaptive experiences and the formation of particular cognitive schemas have also been implicated. For example, the hostile-attribution bias is a tendency of perceiving the world as hostile and other people as intentionally wanting to harm others. People's interpretations may be accurate and functional whereas others may be biased and dysfunctional. Trait anger has also been linked to problems in self-regulation or lack of effortful control.

From trait anger to the anger state. A common framework for studying the link between traits and states is the person by environment model. In the case of anger, this model suggests that an environmental trigger such as a provocation paired with a strong anger trait raises the probability of an experience of state anger. Triggers include social interactions perceived as provocations, especially when these are perceived as intentional. Other less direct triggers include environmental conditions such as heat, noise, or crowding.

Sex differences in anger. No clear pattern has emerged to suggest that men and women differ in their experiences of anger. This is not to say that the provoking situations that lead to anger are the same for men and women. However, sex differences in the social contexts that promote anger have not been clearly delineated either. Anger is more likely to result in physical aggression in men than in women in most social contexts, but not in intimate relationships where research has shown that women are just as likely as their partners to use physical aggression. Relationship concerns may be particularly important to women because of their traditional primary caretaker role. Men, traditionally in their provider role, would show concern for job-related competition or protection of partners. Also, girls are socialized to suppress their anger and therefore would be less likely than boys to express in public environments. Public display of anger or aggression would be less damaging to men who would be seen as affirming their masculinity.

Measuring Anger

Given the distinction between state and trait anger, it is important to distinguish between these two concepts in assessment. Furthermore, research in social cognition, emotion and motivation taken together raise the need to assess a number of facets of anger: the subjective feeling states, cognitive processes, physiological reactions, and expressive behaviors. A third consideration is whether specific measures are needed to assess anger in contextual domains such as domestic situations, work domains, or in other public domains.

The most common method used to assess anger is the self-report questionnaire, which aims to capture a direct measurement of subjective feeling states. Charles Spielberger developed the latest version of his state–trait anger inventory, the STAXI-2, in 1999

(see Spielberger & Reheiser, 2009). Earlier versions of this instrument included the State–Trait Anger Scale (STAS). The state anger scale measures the intensity of momentary anger from mild irritation to annoyance, to rage. The trait scale assesses disposition to anger in terms of intensity and frequency with two correlated subscales referring to angry temperament and angry reaction. Additional research led to the inclusion of three additional scales: Inhibition (Anger-in), Expression (Anger-out) and Control of Anger. The inhibition and expression scales were seen as two poles of a continuum with control in the middle.

Other self-report questionnaires include scales such as the Novaco Anger Scale and Provocation Inventory (Novaco, 1994), which includes descriptions of anger-provoking situations, asking respondents to rate the degree of anger that they would feel if they were placed in that particular situation. This scale format is particularly useful for identifying particular types of triggers and provoking situations.

Consequences of Anger

Intense anger can have negative consequences such as reactive aggression in its various contexts: child and spouse abuse, dangerous driving and road rage, assault, and murder. Dispositions to anger have negative consequences for long-term intimate relationships and vulnerability to illnesses involving the immune system and cardiovascular disease. However, anger can also provide useful information and be constructive. A person may indeed have experienced unfair disrespect, insult, or other injustice, perhaps on a repeated basis. In some cases, the offender may have caused the provocation unintentionally. Expression of a grievance may help repair a social relation in a constructive manner. In some situations, moral outrage may be justified and help discourage unethical behavior.

Dispositions to anger differ in their intensity, varying from the experience of occasional everyday anger to clinical levels that result in severe consequences such as rage, physical aggression, and violence. Although anger itself is not identified as a disorder, it is a feature in several psychiatric disorders. Treatments of anger can target the hostile-attribution bias and the ruminative thoughts with cognitive behavioral therapy (CBT). The aim of CBT is to change a person's maladaptive thought patterns by learning to recognize when irrational thoughts occur. Treatments that address self-regulation focus on having people recognize cues in the social environment that act as triggers or provocations. Another component of treatment is to help people recognize the emotional phenomenology of anger rather than suppressing it.

Future Directions for Research

Researchers will continue to investigate the situational contexts and triggers that give rise to anger. With societal and technological changes such as violent media entertainment and social networking come new forms of provocations and triggers of anger. Various interrelated disciplines have recognized the benefit of addressing psychological problems in a preventive way in early stages of development and in schools. Anger is often addressed within broader areas of emotional control and self-regulation and within specific problem areas such as bullying, road rage, and domestic violence.

Anxiety

Emily N. Boughner

University of Regina

Conceptualization and Measurement

Anxiety as a concept most likely originated in early Greek texts, and has been studied in parallel to the conceptualization of self-awareness. It is a basic emotion involving feeling excessively tense, fearful, or uneasy, especially when anticipating an unknown or unclear future event. Anxiety can be seen as a mood state that is future-oriented, and adaptive or maladaptive depending on the severity and relevance of anxiety present. Anxiety can be adaptive during situations where caution is appropriate, and it can keep one from harm. However, anxiety can be maladaptive when the situation does not require an anxious response, and one occurs anyway. For example, feeling anxious and fearful at leaving the house to go to the grocery store is a maladaptive overestimation of the danger of leaving home, and being in a busy public place.

The contemporary understanding of anxiety is that it is multidimensional, as it can be a state or a trait, and can be of normal or clinical severity. As a state, anxiety may manifest as immediate feelings of nervousness or tenseness about an upcoming future event. As a trait, anxiety is a personality component that involves a person being prone to anxiety even in events that do not require it. Trait anxiety can consist of negative emotions, issues with the body, disruptive behaviors, and disturbed thinking. As well, a distinction between normal and clinical anxiety can be made. Many people feel anxiety, which is normal, but not everyone experiences it in a debilitating manner. There is a clinical class of mental diagnoses with multiple different manifestations of anxiety disorders, such as separation anxiety, or developmentally inappropriate anxiety about separation from parents/guardians; selective mutism, or consistently failing to speak in certain situations, but otherwise able to talk; specific phobia, or anxiety about specific things, such as blood, a situation, or an animal; social anxiety disorder, or a social phobia with anxiety about social interactions; panic disorder, or unexpected rush of fear; agoraphobia, or fear about public transit, open or enclosed spaces, crowds, and being outside the home; and generalized anxiety disorder, or persistent

and exaggerated anxiety about general things. Anxiety can also be substance-induced or a consequence of another medical disorder.

In order to measure anxiety, self-report measures are most commonly used. A list of general subjective measures can be found in *Anxiety 101*. However, a basic issue with self-report measures is that they can be very subjective and not very objective. It is sometimes better to have fewer subjective measures, such as measuring anxiety with physiological and behavioral measures. Some physiological methods include measures such as blood pressure, pulse rate, heart rate, respiration, and brain activity. Behaviorally, anxiety can be measured as avoidance or distressed behaviors, as coded by trained observers. As well, performance measures and the polygraph machine can be used. Anxiety is best measured through more than one method.

Etiology and Theories of Anxiety

The causes of anxiety are complex and not fully understood. However, a few different mechanisms of anxiety have been explained. Anxiety can be learned through a process called *conditioning*, whereby anxiety is associated with an event or object the person has experienced, and the person feels anxiety when faced with that event or object. For example, a person who has been bitten by a dog and experienced pain may now be fearful of all dogs. Similarly, a person can indirectly learn to be anxious when observing an adult who is experiencing anxiety. A parent may be anxious about attending an event, and so the child also learns to be anxious about attending an event.

There are also biological and genetic explanations for anxiety. Humans as a species are already prepared to be anxious or fearful about certain things that threatened survival in the past, such as snakes or heights. Not everyone is fearful of these things, but it is not uncommon for people to have phobias or anxiety about things that threaten survival. As well, genetic influences may also increase a person's risk of anxiety. If a person has a parent with an anxiety disorder, that person has an increased risk of also having an anxiety disorder. However, the two different people may have two different anxiety disorders, and there may be more of a tendency to be anxious-prone in general instead of having the genes for specific anxiety disorders.

There are certain factors that increase the risk of having an anxiety disorder. These include genetics as previously mentioned, but general life stress can also increase a person's risk of developing an anxiety disorder. This can include adverse events in childhood, as well as traumatic events. Temperament may also be a risk factor, such that those who display the trait of neuroticism, which may include worry, fear, anxiety, loneliness, and other moods and states, are more at risk for anxiety.

Mineka and Zinbarg's Contemporary Learning Theory (2006) incorporates genetics, temperament, and both learning mechanisms into a model to explain why some people develop anxiety and others do not. In this theory, there are two criteria that have to be met. First, there is a genetic or temperament aspect plus previous learning experiences that create a vulnerability to anxiety. Second, there must be three different contexts: conditioning, a stimulus, and perceived control. For example, a person has trait neuroticism, and has had

a previous bad experience with dogs. If the person enters into a situation with a poorly trained dog, they may be anxious, fear being bitten, and feel as though they are not in control of the situation.

A second theory, Barlow's Triple Vulnerability Theory (2000), incorporates both the biological and genetic pathways in an explanation for how anxiety develops. The first criterion for the development of an anxiety disorder is a risk or vulnerability factor. The second and third criteria are a specific psychological experience of anxiety and a general psychological factor, such as lack of control, improper parenting style, or negative events.

Associated Illnesses

Anxiety as a concept and as a disorder is related to many other disorders. It is especially common with posttraumatic stress disorder (PTSD), as PTSD was previously considered an anxiety disorder. Both PTSD and anxiety disorders involve worry, and avoidance of thinking about or being in situations. These thought and behavior patterns are especially common in generalized anxiety, agoraphobia, and social anxiety disorders. Anxiety is also related to depressive and bipolar disorders. Both anxiety and depressive disorders involve feelings of difficulty leaving the house and chronic social isolation. Similarly, depression and anxiety disorders feature worry, constant and intense focus on distress, low mood, and feelings of hopelessness. Anxiety is considered a risk factor for major depressive disorder.

Conditions such as coronary heart disease, bowel issues, asthma, and ulcers are often associated with anxiety, such that anxiety is a factor in the development of these disorders. Substance use disorders and anxiety are related as well. Many people may use substances to self-medicate fears and anxieties. For example, a person who has social anxiety may drink heavily before every social gathering to lower anxiety and feel able to socialize.

Finally, some anxiety disorders are related to each other. For example, although social anxiety is also known as social phobia, and as such, is often related to the other phobias. Panic disorders are also common in those persons with phobias.

Related Psychological Concepts

The term anxiety is often used interchangeably with fear and worry; however, they are separate psychological concepts. As previously described, anxiety is a future-oriented mood state with feelings of tenseness or uneasiness. Fear is a reaction to a specific real or perceived danger, and a present-oriented mood state. For example, a person with a phobia about dogs may feel anxious at imagining an encounter with a dog, and feel fear when in the presence of a dog. Fear can involve behavior as a response to a specific danger. Both fear and anxiety are considered to be highly adaptive in different situations.

Worry is not understood as an emotional reaction or response like anxiety and fear. Instead, it is a verbal expression of a thought process focusing more on negatives that may or may not occur. For example, a person may feel anxious about encountering a dog in the future, but worry obsessively over whether or not the dog will bite him or her.

Anxiety is also similar to paranoia, thoughts that are composed of anxieties and fears. Paranoia can be understood as more extreme than anxiety in many ways, as it can lead to delusions. Phobias, a class of anxiety disorders, are related to paranoia. Phobias and paranoia both contain elements of irrational fear and anxiety; however, paranoia also involves mistrust and blame whereas phobia does not contain blame.

Treatment or Reduction of Anxiety

In the past, treatment of clinical levels of anxiety focused more on analysis of danger; presently, the focus of many effective interventions is cognitive and behavioral change. Appropriate anxiety levels present during situations where it is adaptive, such as in dangerous situations, does not necessarily need to be treated. When anxiety is present in a more exaggerated form, such as extreme social anxiety or phobia, treatment is likely required. Teaching individuals coping strategies, such as problem-focused coping whereby a problem is managed or fixed by easing the problem, can be an effective part of therapy for an anxiety disorder. Other coping strategies such as teaching individuals to lessen negative reactions to anxiety-provoking situations can also be effective. A particularly effective therapy is exposure therapy, wherein the individual is repeatedly exposed to the anxiety-provoking event or object, and gradually learns to mitigate their anxious response to it. Relaxation techniques, such as deep breathing, can also be useful in decreasing emotional responses to anxiety-provoking objects and events.

Cognitive behavioral therapies are also effective, wherein the individual learns to redirect their attention away from the anxiety-provoking event or object, and practices positive self-statements. Individuals are taught to restructure irrational thoughts into constructive and positive thoughts, and many clinicians will have the individual practice these methods in real-life situations.

Some individuals who have anxiety may require anti-anxiety drugs to manage their condition. Benzodiazepines are drugs often prescribed to individuals with severe anxiety, as they induce a sense of calmness for the individual. Another set of drugs called beta-blockers can be effective in controlling social anxieties and stage fright. However, some individuals may need a combination of psychological and pharmaceutical therapies in order to overcome anxiety.

Future Directions

Although anxiety is common, clinicians have difficulty understanding and researching the multidimensionality of anxiety, with different manifestations of normal or clinical severity, and state or trait levels. Future research in anxiety may involve developing a theory that can encompass the entirety of anxiety, from genetics to cognition to environmental aspects. The difficulty is finding a single theory able to incorporate all of these aspects in a straightforward and meaningful manner.

Authoritarianism

Anjana Balakrishnan

University of Western Ontario, London, ON, Canada

Definition and a Portrait of Authoritarianism

Authoritarianism – a psychological construct which has been investigated since the nineteenth century – refers to an attitudinal orientation where individuals express hostility toward those who do not conform to an ideal of sameness or an expected way of being (e.g. minorities, deviants, and dissidents). Other characteristics of the authoritarian ideology are excessive concern for the opinions of authority, moral fixedness, preference for the government to be involved in personal matters, and conformist attitudes. In the political sphere, authoritarianism has been used to refer to specific political orientations, e.g. an authoritarian regime. However, in the psychological literature base, authoritarianism is seen in a broader sense and reflects a general orientation toward conformity versus deviance. In this entry, when the term authoritarianism is used it can be considered as equivalent to the term *right-wing authoritarianism* (RWA) which is frequently used by psychologists. Those who strongly endorse authoritarianism display a marked preference for both remaining connected with and valuing their ingroups over outsiders. Additionally, those who are more authoritarian have a greater tendency to endorse prejudice in varied forms (e.g. moral regulation or ethnocentrism). With regard to authoritarian thought processes, higher levels of authoritarianism have been linked with deficiencies in critical thinking as well as a belief in the world as being frightening and risk-laden.

Most research on authoritarianism tends to focus on those high in authoritarianism (i.e. those who demonstrate the most intolerance to difference). However, it should be acknowledged that authoritarianism falls on a spectrum, and those at the lower end (i.e. libertarians or low authoritarians) demonstrate a markedly different set of attributes. Those low on authoritarianism display more tolerance to diversity and support the idea that individuals should govern themselves. Furthermore, these individuals thrive in contexts of value and belief plurality. Unlike the literature on high authoritarians, less emphasis has been placed on studying low authoritarians. It should be noted that the high versus low distinction of authoritarianism is arbitrary, and individuals vary in their level of authoritarianism in nuanced ways.

Theoretical challenges were faced in the early conceptualization of authoritarianism. Teasing apart what authoritarianism is from what it is not and clearly delineating the boundaries of this construct has been a major aim of research. As an illustration, authoritarianism due to its influence in the sociopolitical arena has been viewed as interchangeable with constructs such as *conservatism*. However, endorsing conservatism involves being averse to changing the status quo, whereas endorsing authoritarianism does not mean one is change averse so long as the change is in accord with the goals of the collective. Another example would be that the closely related yet theoretically distinct variable of *social dominance orientation* – a preference in intergroup relations for either equality between groups or hierarchy where the ingroup is superordinate – was initially mistaken as a dimension of authoritarianism. This discrepancy was due to findings that both authoritarianism and SDO predicted outcomes which appeared linked to authoritarianism (e.g. prejudice). However, comparative investigations of SDO and authoritarianism have shown that the two constructs are distinct in terms of patterns of correlations with other variables, scale items, etc. Another challenge has been the creation of adequate measurement tools to aid in the study of authoritarianism because most measures have been unable to balance grounded theory with strong empirical support.

Components of Authoritarianism: An Elaboration

The construct of authoritarianism subsumes three key underlying concepts which are authoritarian aggression, authoritarian submission, and conventionalism. Authoritarian aggression is the idea that authoritarians promote aggressive behaviors toward others when such behavior is supported by authority figures. This aggression is commonly directed toward those who are noticeably different (e.g. a social deviant), but can expand to anyone in the disfavor of authority figures. Authoritarian submission is the belief that members of authority (e.g. religious and political leaders) should be fervently supported. In the case of family, parental figures are seen as credible sources of authority by authoritarians. Some research suggests that while authoritarians do submit to authority, this depends on whether the authority figure has a good reputation and their actions are perceived as being in line with the goal of the collective. The degree of submission shown by authoritarians varies based on the credibility of the authority figure. Lastly, conventionalism is the principle that the existing social norms and order should be maintained.

Sources of and Influences on Authoritarianism

Early theorists posited that authoritarianism stemmed from how parents raised their children. It was believed that parental childrearing styles which involved punishment and inflexible adherence to rules set the stage for authoritarian tendencies. Genetics have also been implicated as a source of authoritarianism, and traits such as religiousness and traditionalism which are part of the theoretical core of authoritarianism as well as the RWA scale itself have shown good heritability. Support for a personality-based genesis of authoritarian tendencies and ideology stem from findings which show that certain Big Five personality

dimensions are antecedents of authoritarianism. To elaborate, lower levels of Openness to Experience – specifically for the intellect facet and to a lesser extent for the openness facet – have been demonstrated to predict greater authoritarianism in large-scale meta-analytic research. Facets of both Conscientiousness and Neuroticism have also been implicated with greater authoritarianism, however these findings need further corroboration.

An environmental influencer of authoritarianism is social learning. To elaborate, individuals from a young age imbibe what authoritarian values are either through explicit teachings of key individuals such as parents, through mimicking idealized others, or through precursors of authoritarianism which stem in adolescence. Education has been implicated as yet another cause of authoritarianism. To expand, higher education is believed to have ameliorative effects in that those graduating from a university display lower levels of authoritarianism. Education both increases the exposure to diverse values and beliefs and enhances individuals' cognitive capacities to handle difference. An alternative account for the education effect is that education may simply be training individuals to demonstrate political correctness in situations of diversity as opposed to causing transformative change toward an innate preference for difference. The explanations delineated above suggest that both intrinsic and external factors play a role in determining authoritarianism.

Cultural Variation in the Expression and Endorsement of Authoritarianism

Across cultures, representative elements of authoritarianism consistently emerge. However, within cultures, individuals fluctuate on a spectrum in terms of their adherence to and endorsement of authoritarian values. Large sample cross-cultural data reported in the World Values Survey offer illuminating insights into how authoritarianism varies and what effects it exerts in different cultural contexts. The take-home message from the cross-cultural data suggests that authoritarianism contributes significantly to generalized intolerance, and that irrespective of the cultural groups involved, authoritarianism drives individuals toward a stance of reducing differences. However, the cross-cultural findings also indicate that in contexts of value and belief diversity, the effects of authoritarianism on being intolerant become exacerbated.

Modern Conceptualization

The modern conceptualization of authoritarianism explicitly acknowledges that the interactive effects between the person with authoritarian predispositions and the environment either trigger or suppress the expression of authoritarian attitudes. To elaborate, the context of being in a threatening situation such as one where individuals diverge in values and beliefs can polarize those with higher authoritarian predisposition toward more authoritarian attitudes. In contrast, those with lower authoritarian predisposition (i.e. libertarians or non-authoritarians) demonstrate more tolerant attitudes. However, some evidence has suggested that highly authoritarian individuals can be conditioned to demonstrate more

tolerant attitudes in spite of their cognitive inflexibility. Using a rigorous experimental design, Karen Stenner (2005) created a condition where participants were led to believe a fake news claim that otherworldly life-forms (i.e. aliens) exist. Those in the alien condition who were higher in authoritarian tendencies were more tolerant in their attitudes, and this is attributed to the idea that aliens represent an extreme outgroup that makes existing outgroups (e.g. minorities) seem more similar. This finding suggests that authoritarianism can be suppressed by emphasizing commonalities between ingroups and outgroups which in turn blurs the "us" vs. "them" boundary.

Measurement Tools and Associated Challenges

Although a host of research tools are available for the study of authoritarianism, only the best-known tools will be described here. One of the earliest and most contentious measures of authoritarianism is the Fascism (F) Scale by Adorno, Frenkel-Brunswik, Levinson, & Sanford. The F Scale is based on the psychodynamic account of authoritarianism where harsh parenting leads to the endorsement of fascist and intolerant beliefs among high authoritarians. The F Scale has been met with criticism on both empirical and theoretical grounds. In terms of empirical critique, the soundness of the scale has been called into question due to item-wording in only the positive direction, *acquiescence bias* – tending to respond in the affirmative – and contrived unidimensionality (i.e. the artificial appearance that all items belong on a single authoritarianism factor). With regard to theoretical critique, it has been argued that the sampling domain of this scale is too large and includes disconnected elements such as sex and objectivity with more central elements such as submission and aggression.

In order to remedy the challenges of the F Scale, researchers have attempted to either fix the F Scale with further test development or to form revised conceptualizations and scales of authoritarianism such as the Dogmatism "D" Scale which taps into individual levels of closed-mindedness and rigidity. At present, the Right-Wing Authoritarianism Scale by Bob Altemeyer is the standard measurement instrument for this construct. The RWA Scale samples from a subset of the domains on the F Scale and it focuses on the components of authoritarian submission, authoritarian aggression, and conventionalism. The RWA Scale empirically outweighs the F Scale given that both positive and negative item-wording are used and test construction theory has been referred to in the developmental stages. However, some criticisms are that the scale creates an artificial typology where more is known about high-scorers than low-scorers, the scale content is ambiguous in that some items tap into multiple domains, etc. One alternative to the RWA Scale is a short questionnaire of authoritarian inclination which asks participants their preference between pairs of terms, e.g. "obey" versus "question" with a preference for the former indicating authoritarianism.

Personality Correlates of Behavioral Inhibition/Activation

Ola Mohamed Ali

University of Western Ontario

Overview

The Behavioral Inhibition System (BIS) and Behavioral Activation System (BAS) describe underlying neurophysiological systems that govern the relationship between one's affective state and behavior, and together comprise Gray's Biopsychosocial Theory of Personality (1981). Broadly speaking, these systems characterize aspects of nervous system functioning that explain individual differences in responsivity to environmental cues, namely motivation and approach behavior. Specifically, the BIS is thought to regulate sensitivity to punishment and regulates approach behavior with the purpose of avoiding or lessening contact with threat, danger or unpleasant environmental cues. On the other hand, the BAS regulates sensitivity to reward and elicits approach behavior with the goal of gaining something desired. Behaviorally, BIS sensitivity is associated with increased perceptions of threat, fear, reticence in novel environments, greater expressions of negative affect, and generally inhibited behavior. In contrast, BAS sensitivity is associated with goal-directed behavior, extraversion, increased perceptions of reward, and greater expressions of positive affect. The BIS and BAS are thought to act antagonistically, where increased sensitivity of one system is often associated with decreased sensitivity of the other. For instance, individuals who are behaviorally inhibited, introverted, and prone to anxiety tend to engage less in potentially rewarding behavior, are less impulsive, and experience less positive emotions in contexts of potential reward. Theoretically, the relative sensitivity of these systems represents two broad and independent dimensions of personality: trait anxiety and impulsivity.

The Behavioral Inhibition System and Trait Anxiety

Historically, the BIS was thought to become activated when threat is encountered and to result in avoidance behavior. However, recent theories emphasize the specificity of BIS activation to approach-avoidance conflicts that arise when the animal is required to

approach a threat in order to achieve a desirable goal; here, the animal has to evaluate the risks against the potential reward in approaching the stimulus. An apparent approach-avoidance conflict leads to the activation of a cascade of processes that are directed at reducing contact with threat, while at the same time achieving the desired goal. This would include inhibition of dominant responses, hypervigilance, risk assessment, and cautious approach behavior. Essentially, BIS activation results in interruption of ongoing behavior as a resolution to the approach-avoidance conflict, and both avoidance and vigilant approach can be viewed as its behavioral consequences. A notable example of BIS activation can be seen in public speaking, an activity that involves an element of social evaluation, often perceived as threatening or unpleasant, but that is also a necessary component in many professional settings. Similarly, novelty can elicit BIS activation, where the unknown stimulus can be both rewarding and aversive, giving rise to the approach-avoidance conflict. For instance, the BIS is activated to resolve the conflict that arises when an animal forsakes safety and ventures into novelty to obtain food, resulting in increased scanning behavior. Accordingly, the BIS can be thought of as consisting of cognitive and physiological components that govern perception and ensuing behavior, respectively. At the cognitive level, BIS activation engages attentional processes, and is associated with sensitivity to unexpected stimuli and detection of conflicts in behavioral tendencies. Consequently, recruitment of these processes results in physiological hyperarousal and/or halting of ongoing behavior.

The BIS is thought to be composed of the septo-hippocampal system which receives input from the prefrontal cortex and projects to brainstem areas such as the locus coeruleus. The functioning of this system is primarily mediated by serotoninergic neurotransmission between structures. Recent studies implicate the hippocampus, the anterior cingulate cortex (ACC) and the amygdala as key players in the BIS system. The hippocampus and ACC are mainly responsible for its conflict monitoring function, and may specifically respond when the approach-avoidance conflict is detected. Increased activation of the amygdala has been observed experimentally in response to threatening and ambiguous stimuli, highlighting the involvement of this area in the BIS's heightened responsivity to threat.

Individuals with elevated BIS sensitivity, then, are highly responsive to cues of potential punishment or threat compared to those with lower BIS sensitivity, exhibiting trait anxiety, or anxiety proneness. This trait is both heritable and stable across time, emerging early in life and persisting throughout development. Indeed, behavioral inhibition, a relatively stable trait that correlates with neurobiological measures of BIS activation, emerges as early as the second year of life, and describes children who tend to display marked fear, diminished activity, and heightened vigilance in unfamiliar situations. Moreover, elevated BIS sensitivity correlates positively with measures of neuroticism and negative affectivity, personality constructs that relate to greater reactivity to stress and a tendency to experience negative emotions.

The Behavioral Activation System and Impulsivity

Aversive motivation is certainly not sufficient to explain individual differences in approach behavior, and must be complemented by a system that governs appetitive motivation. The Behavioral Activation System (BAS; also referred to as the behavioral approach system and

behavioral facilitation system) underlies sensitivity to reward and facilitates engagement with the environment with the goal of achieving something desired. Once a rewarding stimulus is perceived, two components of BAS that facilitate approach are initiated: motor activity toward the desired object or situation and positive affectivity. Stimuli that activate the BAS are inherently and potentially rewarding, and include food, mating, and novelty. Moreover, the BAS may be activated to facilitate active avoidance of possible punishment, for instance through aggressive attack of a potential threat. Individuals with elevated BAS sensitivity display persistent pursuit of desired goals, continually desire new rewards, are more willing to approach a potentially rewarding stimulus on impulse, and experience greater positive emotions in response to reward. Accordingly, these individuals are generally described as extroverted, whereby their sociability and novelty-seeking can be attributed to elevated BAS sensitivity.

The neurobiological mechanisms of the BAS are not as well understood as those of the BIS. However, there is converging evidence for the involvement of a dopaminergic pathway between the "reward centers" in the brain, namely the ventral tegmental area, nucleus accumbens, and ventral striatum (described in great detail by Richard Depue and William Iacono (1989)). These areas project to other areas that are involved in motor function and emotional processing (e.g. prefrontal cortex and amygdala), suggesting that they may initiate the locomotor and affective functions of the BAS.

BIS/BAS and Psychopathology

Consistent with the view that psychological disorders lie on a spectrum of normal to abnormal behavior, a suite of disorders manifests at the extreme ends of BIS and BAS sensitivity. Anxiety disorders are characterized by extreme worry and fearfulness of the future (as in Generalized Anxiety Disorder), as well as certain situations (as in Social Anxiety Disorder, Separation Anxiety Disorder, Panic Disorder and Agoraphobia) and objects (as in Specific Phobia). Accordingly, extreme BIS sensitivity is thought to underlie these disorders and explain why clinically anxious individuals tend to perceive threat in seemingly benign stimuli and are more likely to display avoidant behavior and to experience negative emotions. In contrast, elevated BIS sensitivity *accompanied* by decreased BAS sensitivity have been linked to depressive disorders, and this pattern is suggested to explain the negative emotions reported by depressed patients as well as their lowered responsiveness to reward and decreased motivation to pursue rewarding stimuli. This latter aspect is also referred to as anhedonia, a hallmark symptom of Major Depressive Disorder. Attention-deficit hyperactivity disorder (ADHD) is characterized by disinhibited behavior and impulsivity that are thought to result from reduced BIS sensitivity, whereby there is insensitivity to cues of threat, as well as elevated BAS sensitivity, whereby there is heightened sensitivity to reward. Consequently, the individual displays a greater tendency to seek and engage in rewarding behavior, and fails to regulate (and halt) ongoing behavior when threat is presented. Extreme BAS sensitivity has been suggested to underlie mania, a component of Bipolar Disorder that is characterized by clinically impairing levels of goal-directed activity, reward seeking, and elation. Accordingly, these patterns of association between BIS/BAS

sensitivity and psychopathology underscore the value of studying the functioning of both systems when examining their behavioral correlates.

Measurement

Conceptualization of the BIS and BAS offers a theoretical framework for explaining individual differences in motivation, and the personality dimensions that arise from these differences. Since the emergence of this theory, supporting evidence from self-report, psychophysiological, and neurobiological measures has been reported. The most widely used assessment tool for studying the BIS and BAS sensitivity is the BIS/BAS scale developed by Charles Carver and Teri White (1994). This self-report measure consists of 24 statements that tap elements of behavioral inhibition and activation. Respondents are asked to rate how much they agree with each statement on a four-point scale, with "1" being complete agreement and 4 being complete disagreement. The BIS scale consists of seven items that assess the individual's reported likelihood of experiencing anxiety across situations. The BAS items fall into three scales that are empirically supported elements of behavioral activation: Drive, Fun Seeking, and Reward Responsiveness. Lower scores reflect greater endorsement of items and heightened sensitivity for each scale.

Psychophysiological measures generally tap sympathetic and parasympathetic nervous system activation that are hypothesized consequences of BIS and BAS activation. Outputs of these systems include cardiac reactivity, measured using electrocardiography (ECG), and electrodermal responding, also known as skin conductance. These measures are usually done during tasks of reward and frustrative non-reward, and therefore may not necessarily index state sensitivity of the BIS and BAS, but rather their context-dependent reactivity. As such, these measures provide independent information on BIS and BAS activation from that obtained using self-report scales.

The advent of brain imaging technology has further enabled investigation of neural correlates of the BIS and BAS, and allowed verification of the early theories about implicated brain areas. Electroencephalography (EEG) is a cost-effective tool for measuring instantaneous activity of the brain systems proposed to underlie the BIS and BAS functioning. Brain regions involved in BIS functioning are thought to be lateralized to the right hemisphere, whereas those involved with the BAS are lateralized to the left. Accordingly, behavioral withdrawal will be associated with greater *right* resting frontal cortical activity, and approach behavior will be associated with greater *left* resting frontal cortical activity. Together, this pattern of activation is referred to as "frontal asymmetry." Finally, functional magnetic resonance imaging (fMRI) allows direct measurement of the activation of specific brain areas during reward and threat tasks, offering further insight into the neural processes governing the BIS and BAS.

To sum up, the BIS and BAS comprise structurally distinct neurophysiological systems whose activity can be measured independently, and appear to govern different facets of approach behavior. These systems are activated differentially across individuals and correspond to independent dimensions of personality. Abnormalities in their relative sensitivity are associated with several psychological disorders, and identifying their contribution to these disorders can guide both prevention and intervention.

Big Five Model of Personality

Sarah E. Babcock and Claire A. Wilson

The University of Western Ontario

Overview

The Big Five (sometimes referred to as the Five Factor Model) is a widely accepted model of human personality traits. It includes five broad dimensions, also called factors, used by many psychologists to describe and label personality characteristics. These factors are thought to represent the basic underlying structure behind all personality traits. The Big Five consists of five broad factors of personality traits: *Extraversion, Agreeableness, Conscientiousness, Neuroticism,* and *Openness to Experience*. This concept of personality, as we currently understand it, has a long history with many contributors. The Big Five has its early roots in the late 1930s, where psychologists turned to natural language as the source of identifying attributes for a personality naming structure. The work began with a lexical approach of extracting all personality-related terms from the dictionary; this *lexical hypothesis* logic suggests that most of the socially relevant personality characteristics are encoded in our natural language. At first there were a multitude of terms, with words in the many thousands, however, through the work of multiple research groups over many years, psychologists identified common themes in the language, and the identification of specific themes (clusters of words) began to emerge. While the specific labels applied to these dimensions varied between researchers, the underlying themes were extremely similar and a consensus among researchers became more pronounced.

While sometimes referred to as a theory of personality, the five factors were determined through exploratory factor analysis, a statistical technique used to analyze ratings of correlated personality traits. As such, the Big Five is more appropriately understood as an empirically-based model of personality. With the same set of five relatively independent factors appearing consistently across several studies, this factor structure was refined and eventually became known as the Big Five (Goldberg, 1981). The title of "Big Five" was given to emphasize the broadness of each of the factors, and does not imply that personality can be reduced only to five traits. Instead, the five dimensions represent personality at its broadest level, with each dimension summarizing a number of distinct personality characteristics.

The five factors of this model are orthogonal, meaning that getting a high or low score on any one of these traits does not necessarily determine a specific score on any of the other traits. The factors are therefore independent, and in general do not highly correlate with one another. This particular model is extremely useful and well recognized, as it provides a robust and comprehensive framework for describing and comparing individuals. This characteristic makes this relatively short list of personality dimensions very valuable, because it encompasses a wide range of traits that can summarize the majority of measureable personality characteristics. As a result, the Big Five model is utilized as the underlying factor structure for a variety of personality assessments, one of the most predominant assessments being the *Revised NEO Personality Inventory* (NEO-PI-R). The full version is composed of 240 questions intended to measure the Big Five personality traits, as well as six subordinate dimensions (called facets) of each main personality factor.

Factor Stability and Heritability

The Big Five personality dimensions provide investigators with a group of highly replicable and reliable factors that parsimoniously and comprehensively describe most individual differences. One important consideration when assessing reliability is the stability of the individual differences. Specifically, this refers to the extent to which individuals maintain the same rank-order along the different dimensions over time. Therefore, the way an individual scores on a particular factor (high vs. low) will remain consistent over time, even if the individual's overall score changes on future assessments of this factor. Research using both self-report and observer ratings show strong evidence that the Big Five are stable over time. The stability of the Big Five has been studied over a number of years ranging from three-year studies to 30-year studies, and all demonstrate similarly high stability values; specifically, the stability tends to be particularly high throughout the adult years. In addition to longitudinal stability, this factor structure has also maintained its effectiveness across cultures. The Big Five factor structure shows stability in many rigorous cross-language replication tests, demonstrating broad generalizability across cultures, including in Germany, Italy, and Japan.

It is well accepted in personality research that genetic factors account for approximately 30–50% of the variance in personality traits. The heritability of the Big Five has been studied extensively, and overall, the heritability estimates are quite substantial, ranging from 43% to 54%. While research on the genetic influences of all five traits is plentiful, the majority of research in this area has focused on Neuroticism and Extroversion. Research suggests that Neuroticism and Extroversion have very strong underlying genetic components. In contrast, research on the heritability of Agreeableness is quite inconsistent, suggesting a strong genetic underpinning may not be as clear in this trait.

Extraversion

Extraversion as a personality trait is defined as a keen interest in other people and external events, and the willingness and confidence to try new things. The broad dimension of

Extraversion incorporates more specific personality traits such as talkative, energetic, and assertive and is associated with the tendency to seek stimulation from the company of others.

The bipolarity of the dimension can be understood as people-oriented and outgoing versus solitary and reserved. At the extremes, those who demonstrate very high Extraversion can often be perceived as domineering or attention seeking, while very low Extraversion results in a more reflective, reserved personality that may be perceived as aloof. The NEO-PI-R measures the following six underlying facets within the Extraversion dimension: warmth, gregariousness, assertiveness, activity, excitement seeking, and positive emotion. The type of items you might see on an assessment measuring Extraversion would look something like "*I am comfortable starting conversations with strangers*" or "*I enjoy attending parties.*"

Agreeableness

Agreeableness as a personality trait is defined as the extent to which individuals get along with others, and how compatible they are with other people. The dimension of Agreeableness encompasses personality traits such as cooperative, warm, and considerate and is associated with the tendency to be generous and sympathetic toward others.

Agreeableness can be understood as friendly and compassionate at one end of the spectrum and analytical and detached at the other. Those at the highest level of the spectrum of Agreeableness can sometimes be perceived as naïve or passive, while those very low in Agreeableness can seem argumentative and competitive. The NEO-PI-R measures the following six underlying facets within the Agreeableness dimension: trust, straightforwardness, altruism, compliance, modesty, and tendermindedness. The type of items you might see on an assessment measuring Agreeableness would look something like "*I am interested in other people*" or "*I sympathize with other people's emotions.*"

Conscientiousness

Conscientiousness as a personality trait is defined as being careful, self-disciplined, and vigilant. Conscientious individuals are characterized by thinking carefully before acting, and as having a strong desire to do a task well. The dimension includes personality traits such as efficient, dependable, and organized.

The bipolarity of the dimension can be understood as organized and efficient versus disorderly and spontaneous. At the extremes, those very high in Conscientiousness can sometimes be perceived as obsessive and stubborn, while those low in Conscientiousness are thought to be easy-going, but sometimes unreliable and chaotic. The NEO-PI-R measures the following six underlying facets within the Conscientiousness dimension: competence, order, dutifulness, achievement striving, self-discipline, and deliberation. The type of items you might see on an assessment measuring Conscientiousness would look something like "*I like to follow an agenda*" or "*I get my tasks done early.*"

Neuroticism

Neuroticism as a personality trait is defined as the tendency to be in a negative emotional state and experience unpleasant emotions such as worry, anger, frustration, and envy. It is often characterized by an individual's degree of emotional stability and impulse control. The dimension includes traits such as being tense, moody, and anxious.

Neuroticism can be understood as sensitive and nervous at one end of the spectrum versus secure and confident at the other end. Those who exhibit higher levels of neuroticism tend to appear reactive, unstable, and insecure, while individuals low on neuroticism seem stable, calm, and unconcerned. The NEO-PI-R measures the following six underlying facets within the Neuroticism dimension: anxiety, hostility, depression, self-consciousness, impulsiveness, and vulnerability to stress. The type of items you might see on an assessment measuring Neuroticism would look something like "*I am very easily bothered by things*" or "*My mood changes often.*"

Openness to Experience

Openness to Experience as a personality dimension generally refers to how willing individuals are to make adjustments in their lives and how open they are to new ideas and situations. It is characterized by creativity, intellectual curiosity, and having a wide variety of interests. The dimension includes personality traits such as imaginative, curious, and insightful.

The bipolarity of the trait can be represented by curious and inventive at one end of the spectrum versus consistent and cautious at the other end. Those extremely high in Openness might be perceived as lacking focus or being unpredictable, while those very low in Openness are often seen as closed-minded and overly pragmatic. The NEO-PI-R measures the following six underlying facets within the Openness to Experience dimension: fantasy, esthetics, feelings, actions, ideas, and values. The type of items you might see on an assessment measuring Openness to Experience would look something like *"I am very creative"* or *"I am eager to try new things."*

Criticisms and Additional Considerations

Labeling people with regard to their Big Five personality dimensions cannot alone provide an explanation of the personality processes that underlie and account for the trait phenomena we observe in individuals. It is a model of the personality attributes that demonstrate individual differences, and as such, it is descriptive rather than explanatory. Furthermore, while the Big Five provides a comprehensive organizing structure for most personality attributes, it is not perfect. The major criticism surrounding the model is concerning the number of factors; some researchers suggest that evidence shows there should be additional dimensions, while others suggest fewer would be better.

One of the criticisms of the Big Five is that the model has too many factors, and that personality can be more succinctly categorized into fewer dimensions. Arguably, the best-known competing model is the Eysenck Personality Inventory, which consists of only three factors, conceptualized as biologically-based independent dimensions of temperament. These three factors are: Extroversion/Introversion, Neuroticism/Stability, and Psychoticism/Socialism. It is clear that there are conceptual overlaps with the Big Five, however the argument for this model is that the additional breakdown of the primary factors is unnecessary.

On the contrary, there is a strong argument that the Big Five is too limited and that additional factors must be added to enable a comprehensive assessment of personality. One predominant alternate model is the HEXACO. This model was suggested based on the findings of lexical studies in European and Asian languages, which suggested that full replications of the Big Five model were not possible as a result of a missing dimension. The HEXACO is built upon the foundation of the Big Five, however this model conceptualizes personality in terms of six dimensions rather than five. It is unique primarily because of the addition of the *Honesty-Humility* dimension not addressed by the Big Five model, and consists of the following six dimensions: *Honesty-Humility (H), Emotionality (E), Extraversion (X), Agreeableness (A), Conscientiousness (C),* and *Openness to Experience (O)*. Like the Big Five, the model was developed using trait-taxonomy methods, and each factor is composed of traits with characteristics indicating high or low levels of the factor.

The Big Five has been studied extensively for many decades and has consistently been at the heart of personality research. In recent years, however, there has been an influx of research focusing in on the concept of the General Factor of Personality (GFP), which suggests that much like the general factor of cognitive ability, *g*, there is a hierarchal structure of personality with the GFP serving as the apex of personality factors. Future research in the realm of personality and the Five Factor Model may soon see a shift, moving from this traditional multi-factor model to a general factor model outlining human personality traits.

Cognitive and Personality Correlates of Achievement

Michelle A. Drefs and Gabrielle Wilcox

University of Calgary

The link between learning and both intelligence and personality has been of longstanding scholarly and scientific interest, with roots dating back millennia to early philosophical discussions concerning individual differences in human performance. Within the more recent history of cognitive and personality measurement (beginning around the early 1900s), advancements have been made in understanding which abilities and characteristics are of most importance to optimize academic trajectories and explain underperformance. Specific to cognition, research has consistently supported measures of intellectual ability (i.e. IQ) as good predictors of school achievement. Initially, global IQ scores were used to categorize who would and would not benefit from education and training, with certain groups deemed "untrainable." With advancements in measurement and practice, IQ scores have been used to guide a greater range of educational and instructional decisions. Researchers are beginning to more fully understand well-developed cognitive processes, which can be harnessed to support educational success, as well as under-developed (or disordered) processes, which contribute to the intractable learning difficulties and underperformance characteristic of certain populations (e.g. individuals with a specific learning disability).

There is considerable evidence to suggest that being a highly successful learner is more dependent on cognitive ability than on non-cognitive (personality) variables, such as self-confidence, conscientiousness, and achievement motivation. However, personality characteristics are also a significant determiner of several achievement outcomes. Our current understanding of the personality-achievement link is likely somewhat limited given that personality factors have been given less attention within educational contexts, particularly when compared with other factors (e.g. cognitive, motivational, environmental). However, there are notable increases in educational research and practice in which consideration is conjointly given to cognitive- and personality-related factors.

Intelligence's Contribution to Academic Achievement

Intelligence is generally defined as one's capacity to learn, reason, plan, and problem-solve. Brain imaging and neuropsychology studies have demonstrated that there are neuropsychological, functional, and sometimes anatomical differences between students who perform well academically and those who struggle. For example, poor readers are more likely to show activity in brain areas that are less efficient in processing written material (e.g. over-reliance on the right hemisphere for decoding) and fail to effectively recruit areas necessary for proficient reading (e.g. occipital lobe for orthographic processing).

More recent work, adopting multifaceted models and measures of intelligence, has furthered our understanding of the link between cognition and achievement. One existing theory of intelligence, the Cattell-Horn-Carroll (CHC) theory, which conceptualizes general intelligence (often referred to as "g") as being composed of nine broad abilities each made up of narrow abilities, has provided insight into the cognitive correlates of academic achievement. Recent findings suggest that while the broad abilities provide average predictive validity, the narrow abilities are actually better suited to understanding achievement in specific academic areas and in informing intervention planning. For example, specific narrow abilities, such as processing speed and short-term memory, predict basic reading skills. Further, the strength of the relationship between a cognitive correlate and a specific area of academic achievement (e.g. decoding, vocabulary, comprehension) varies by age and may be differentially important for individuals from different cultural groups.

Contributions of Executive Functioning

Executive functioning, as a more recently examined contributor to achievement, is a constellation of skills that work together in helping individuals complete tasks by directing other cognitive processes, and it includes multiple components such as inhibition, planning, monitoring, shifting, and flexibility. Executive functions organize, direct, and co-ordinate the other thinking functions as an individual completes a task. While research examining the relationship between specific areas of executive functioning and academic achievement is still limited, we know that at least some components of executive functioning affect academic performance. Consequently, children who have intellectual and academic skill strengths sometimes perform poorly in school due to poor executive functioning (e.g. not turning in work, not checking work for errors, etc.). The role of executive functioning in the acquisition of academic skills appears to be of particular importance in primary school-aged children, with the most growth in executive functioning occurring during early elementary school.

Contributions of Working Memory

Working memory is often listed as an executive function, but its significant contribution to academic achievement warrants examining it specifically. Working memory is the capacity to hold information in one's mind and to manipulate it, while short-term memory solely relates to storage and retrieval. Working memory is important in many areas of academic achievement, and some studies have found it to predict future academic

performance better than IQ. For example, impaired working memory performance predicts a mathematics learning disability as well as previous math skills, and working memory performance is a strong predictor of future math performance. Children with compromised working memory struggle with the routine demands of academic activities such as following multi-step directions and recalling previously learned information, resulting in missed learning opportunities and academic failures, which have a detrimental impact on overall academic outcomes.

Personality's Contribution to Academic Achievement

While it is clear that cognition plays a significant role in academic outcomes, certain personality characteristics have also been identified as important predictors of a range of learning outcomes (academic performance, academic engagement, job performance). While there are multiple theories of personality, the Big Five is one of the most researched and well-known theories. It is composed of five attributes, each of which is a continuum: openness (curiosity, open to new ideas), conscientiousness (organized, dependable), neuroticism (anxious, temperamental), extraversion (outgoing, talkative), and agreeableness (affable, kind). Conscientiousness is a strong predictor of academic achievement from preschool through postsecondary. Additionally, openness is positively correlated with achievement. However, extraversion and agreeableness are not related to academic achievement, and neuroticism is negatively correlated with academic achievement.

It appears then that how an individual thinks about and approaches learning (in terms of one's personality) matters – and some personality characteristics matter more than others. As such, both intelligence and personality are important contributors to academic success. However, personality is arguably the more "important" of these two factors. While both personality and intelligence are considered stable factors, personality is somewhat more amenable to intervention. That is, there is evidence that personality can be shaped and influenced more than intelligence. For example, Carol Dweck has found that the adoption of a growth mindset, the belief that intelligence can be developed, is linked to increases in the value placed on learning, resilience in the face of setbacks, effort, and persistence. Ultimately, the integration of a growth mindset into one's beliefs has been found to increase academic outcomes, particularly for groups at risk for low achievement.

Future Directions

A small but growing number of researchers are beginning to examine learner profiles to identify person-specific factors impacting academic outcomes. Representing a significant departure from the more typical approach of seeking to identify general patterns of performance at the group level (i.e. the types of cognitive and personality correlates of achievement initially described), this approach focuses on the identification of strengths and weaknesses (PSW) specific to each learner. To date, this research has primarily focused on identifying cognitive and academic profiles in individuals with specific learning disabilities. The PSW approach holds broader promise, however, as a multimethod assessment approach

that allows for greater consideration to be given to both cognitive and non-cognitive factors. Patterns of discordance, defined as significant differences between performance on cognitive processing tasks and related achievement measures, are identified and then further investigated and verified via ecological markers (e.g. teacher and parent reports). In the instance of an individual who has working memory deficits, ecological markers could also point to personality characteristics that contribute to a difficulty in flexibly maintaining and updating information in active memory (e.g. perseveration). Such approaches are not without controversy as parallels have been drawn to the largely unsuccessful aptitude-by-treatment (ATI) approaches of the early 1980s. However, these approaches are appealing because they appear better positioned to examine the heterogeneity of abilities and personal characteristics that contribute to academic success. Proponents of the PSW approach additionally argue that it yields a comprehensive performance profile that can that be used in the design of interventions programs to enhance academic outcomes.

Further study of the link between achievement and both cognition and personality will need to reconcile the increasingly narrowing distinction between these three areas. While simple distinctions (e.g. intelligence as a hard-wired general capacity versus achievement as an acquired expertise in a domain) were useful in early investigations in this area, there is increased recognition that intelligence, personality, and achievement are not discrete entities but rather constitute highly interrelated skills and processes. An example of the difficulty in parsing cognition from achievement is the often-cited criticism that intelligence tests measure, at least in part, an individual's past exposure to certain cultural activities and learnings (e.g. mazes, vocabulary). There is also the well-established finding that some tasks on intelligence tests are susceptible to a practice effect in which repeated exposure to test items results in *learning* of certain test processes and increased scores over multiple test administrations. There are also multiple examples of the difficulty in parsing what is a cognitive ability from a personality characteristic – take, for example, self-regulation. Viewed as a *style*, it is an integral aspect of personality. Viewed as a *complex skill*, it is linked to executive functioning. Perhaps the quintessential example is emotional intelligence (EI). Various models exist in which it is conceptualized as a form of intelligence, a personality-like trait, or a combination of the two (mixed model).

This overlap between cognition, personality, and achievement becomes even more pronounced when considering the shifting focus of schooling. Whereas education has long emphasized mastery of a specific school curriculum, education for the twenty-first century learner focuses on equipping students with the knowledge and skills needed to be life-long learners. Critical thinking and problem-solving, long equated with cognition, are now being identified as central educational outcomes and learning objectives. Non-cognitive factors, such as personality, are also growing in popularity with the education community. It is now commonplace for educational standards to focus on the development of both academic and personality-type goals emphasizing the development of students as *engaged thinkers* and *ethical citizens*, who possess an *entrepreneurial spirit*. Lipnevich and Roberts (2012) have noted that non-cognitive factors have been incorporated into national curriculums and international assessments that, in turn, influence educational and economic policies (e.g. PISA). Future directions thus include not only a more integrated, multimethod study of cognitive and personality correlates of achievement but also the greater inclusion of cognitive and personality learnings as educational outcomes.

Compassion

Jacobus (Kobus) G. Maree[1] and Annamaria Di Fabio[2]

[1] *University of Pretoria, Pretoria, South Africa*
[2] *University of Florence, Florence, Italy*

Definition of Compassion

Most people have witnessed or perceived the suffering of others or have themselves been hurt by others, emotionally as well as physically. Peoples' responses when this happens differ widely. Compassion or co-suffering – from the early Latin *com* (with) and *passus*, the past participle of *patior* (to suffer or endure) and the late Latin *cum* (with) and *compassio* (sympathy) – is widely regarded as an exceptional virtue. While compassion is generally considered to be exclusive to human beings, there is proof that some animals (e.g. chimpanzees, elephants, and cats) also display compassion towards other members of their species.

Compassion means to be aware of the suffering or pain of someone else, to feel with someone else, to consider oneself as being in the same position as someone who is experiencing hurt, pain, sorrow, grief, or misery. Compassion also denotes a desire followed by appropriate action to alleviate or moderate the pain and suffering of the sufferer and to help the person in need, pain, or distress. The statement, "I will fetch your family from the airport and take care of your children so you can focus on arranging your mother's funeral," is an example of compassion.

Compassion has nine dimension, all of which are related to the concept of personality. First, it has a focus dimension: the compassionate person shows a keen interest in the plight of the sufferer. Second, it implies an emotional involvement with the sufferer (feeling with the sufferer). Third, it has an observational dimension (observing suffering). Fourth, it has an attitudinal dimension (displaying empathy or strong feelings of sympathy towards the sufferer). Fifth, it has a cognitive dimension (assessing what is happening to the person and trying to make sense of the suffering; being able to recognize or identify the feelings of others). Sixth, it has a volitional dimension (displaying the will to do something about another person's suffering; to help the person or be useful to her or him). Seventh, it has a communication dimension (feelings of empathy are conveyed to the sufferer). Eighth, it has a behavioral or an actionable dimension (believing the situation warrants an attempt

to try and change it and actually taking action to alleviate the person's suffering). Ninth, it has an interactive dimension (communication takes place between the compassionate person and the sufferer).

Goetz, Keltner, and Simon-Thomas (2010) found that compassion is associated with different behavioral manifestations and physical responses. The authors distinguish between compassion as a state and as a trait. Both can be linked to views on how compassion evolved. First, compassion is considered a caregiver's (parental) response to the need to protect their progeny. Second, it is believed that compassion developed because it was thought that it increased a person's chances of selection during the mating process. Third, compassion is considered a desirable trait as it enhances relationships between people.

Because of the deep sense of understanding and insight that is generated through compassion, it can sometimes be felt even for someone who has hurt or insulted one. Placing oneself in the position of the other person and understanding the reason for his or her actions or attitude may make it possible for the "victim" to forgive the "perpetrator" and move on with his or her life. Showing compassion can also have substantial benefits for "forgivers." It can make them happier (intrapersonal effect), more capable of establishing and maintaining good interpersonal relationships, more at peace with themselves, and better able to adapt to change and deal with stress. Forgiving also impacts their health positively by, for instance, lowering their stress levels, bringing down their pulse rate, and lowering their cholesterol levels.

Measuring Compassion

The first measure developed to assess compassion was Sprecher and Fehr's Compassionate Love Scale (Sprecher & Fehr, 2005). It consists of 21 items and measures attitudes (towards others) in respect of feelings, thinking, and behavior focused on caring and support for others, including a desire to understand and help others when they are most in need of help. Respondents rate each item on a 7-point Likert scale response format anchored by 0 (not at all true of me) and 7 (very true of me). Other instruments were later also developed to measure compassion. The idea was to design brief scales such as the Santa Clara Brief Compassion Scale (SCBCS) (Hwang, Plante, & Lackey, 2008), which is a shorter version of the Sprecher and Fehr Scale. The SCBCS has only five items, and it, too, uses a 7 point Likert scale response format anchored by 0 (not at all true of me) and 7 (very true of me). The Martins, Nicholas, Shaheen, Jones, and Norris (2013) Compassion Scale (CS) was another new scale. The CS has 10 items and uses the same format as the two scales mentioned above. It measures compassion in terms of the perceived capacity to be moved by the suffering of others and the desire to help alleviate their suffering.

Similarities Between Compassion and Other Constructs

Compassion as a construct is closely related to "empathy" (from empathize: associate or identify with the pain of someone else; feel for someone; the indirect or secondary experience of another person's suffering). However, compassion implies active response to another's

suffering; action or the desire to take action to lessen or ease the suffering of another person. Empathy, on the other hand, implies strong feelings marked by the ability to put yourself in another person's situation emotionally, cognitively, or experientially: "I hear what you say"; "I understand what you are going through"; "I can see why his behavior upsets you so much." Empathy thus denotes emotional, cognitive, or experiential action only; a physically passive state characterized by inaction. Compassion is also closely related to "sympathy" (from sympathize: to be in sync with, responsive to, sensitive or sympathetic to or in harmony with another person; to be conscious or aware of the suffering of others: "Please accept my condolences on the passing of your father"; feeling how another person feels: "I feel sympathy (sorry) for you/your loss because I also lost my child two years ago"). Compassion often kindles empathy and sympathy and enables the compassionate person to look away from his or her own pain and focus on the pain of others. In other words, it is a form of self-healing or self-therapy. The importance of also displaying compassion towards oneself and one's own suffering as an aspect of compassion is, however, often overlooked (Maree, 2016, 2017).

Explaining Compassion

Like other traits, compassion can, to some degree, be inherited. If children, for example, are raised in an environment where compassion is nurtured and valued, they themselves may more easily become compassionate. Compassion is a quality that is valued in all major religions. Experiencing genuine attachment to primary caregivers (e.g. parents), or being raised in a religious atmosphere that values compassion, is conducive to the development of compassion. Likewise, transformative experiences such as attending religious gatherings, going to church, participating in religious rituals, or experiencing pain or suffering may promote feelings of attachment to others (Lopez, 2015).

Children may acquire compassion through social learning (i.e. growing up in a context where compassion is valued and displayed by members of the community) (Lopez, 2015). Compassion may also develop at a subconscious level as a result of early life experiences (any psychologist who has elicited clients' earliest recollections will confirm this). Compassion as seen from a psycho-dynamic perspective is associated with the attainment of a life-long theme that characterizes a person's conscious and subconscious actions and that fosters a deep desire to actively master the suffering that she or he suffered early in life (Maree, 2014, 2016, 2018, 2019).

Personality Correlates of Compassion

Among personality traits, compassion is associated with agreeableness. It relates to the perception of being kind, sympathetic, cooperative and warm, and reflects individual differences in co-operation and cordiality. Individuals who are less agreeable are usually less interested in others' well-being and have less empathy. They are less willing to help others and show less compassion because they are skeptical about the problems experienced by and the motivations of others. They are more suspicious and unfriendly, and they prefer to compete rather than collaborate with others.

Compassion is also associated with a prosocial personality, which can be defined as a permanent tendency to consider the welfare of others, to display empathy towards others, and to behave in a manner that is beneficial to others. Compassion is thus associated with prosocial behaviors aimed at benefiting others and society as a whole. This includes helping, sharing, and co-operating.

Likewise, compassion is linked to individual characteristics such as emotional–social intelligence, which, it is generally agreed, predicts success in life more accurately than aptitude or IQ tests. Many virtues associated with emotional–social intelligence (e.g. empathy, a caring attitude, being attuned to other people's emotions, having a sense of social responsibility and sympathy) are also strongly linked to compassion (Maree, Elias, & Bar-On, 2009). Similarly, compassion is linked to social responsibility. Compassionate people are generally eager to find practical ways to help the disadvantaged, that is, to make social contributions. This may manifest in involvement in their communities, in facilitating social justice, and in uplifting individuals or groups whose existence and well-being depend on the goodwill of others (Maree, 2014).

Mother Teresa of Calcutta, now Saint Teresa of Calcutta, who received the Nobel Peace Prize for her work with the dying and the destitute, epitomizes the deepest kind of compassion. She continues to inspire many millions of people around the world to show compassion to others.

Enhancing Compassion

Specific training has been designed and developed to enhance compassion, including strategies to enhance the awareness of present-moment experiences and to promote curiosity and openness to inner experiences. This training has increased mindfulness and happiness, decreased worry and emotional suppression, and enhanced altruistic behavior. The increased altruistic behavior after compassion training has been linked to changed activation in regions of the brain associated with social cognition and emotion regulation, such as the inferior parietal cortex and the dorsolateral prefrontal cortex. These results provide evidence that compassion is associated with the neural system and its involvement in understanding the suffering of others (Weng, et al., 2013).

Compulsive Personality

Laura Henley and Emma A. Climie

Werklund School of Education, University of Calgary

Compulsions are repetitive behaviors (e.g. washing, checking) and/or mental acts (e.g. counting, reviewing) that an individual performs in response to obsessive thoughts or rigid rules (American Psychiatric Association [APA], 2013). Compulsions, which are closely linked with obsessions, are typically engaged in with the aim of reducing feelings of anxiety associated with obsessive thoughts (e.g. washing hands to reduce anxiety associated with thoughts of contamination). Compulsions are often unrelated to the obsessive thoughts (e.g. arranging items in order to protect a loved one) or are done in excess (e.g. washing hands for hours each day).

Obsessive–compulsive (OC) symptoms have a strong genetic influence; however, little is known about the specific genes involved. Individuals with OC symptoms are typically influenced by multiple genes, which combine to produce an additive effect, rather than one specific gene holding responsibility (Taylor, 2011). OC symptoms are often associated with the onset of a stressful life event such as becoming a new parent, having a stressful job, or being exposed to a traumatic event. There are several key brain structures that are implicated in OC symptoms; for example, individuals with OC symptoms often display hyperactivity in the orbitofrontal cortex and caudate. Other affected areas include the anterior cingulate cortex, thalamus, amygdala, and parietal cortex.

Types of Compulsions

There are a number of types of compulsions, including acts related to the need to satisfy general, social, or physical compulsions. The most common types of compulsions include:

- *Washing/cleaning*: Related to fears of an individual contaminating either themselves or others. When this occurs, the individual will engage in hand or body washing rituals repeatedly throughout the day.

- *Checking/rechecking:* Related to excessive doubt and worrying over safety. Individuals will spend many hours each day checking items such as locks, switches, and appliances.
- *Ordering/rearranging:* Often in response to symmetry obsessions. Individuals will feel a strong need for uniformity leading to the ordering and arranging of various objects.
- *Counting:* Individuals may consider a particular number of significance and then engage in compulsive behaviors to the number of times that is significant (e.g. counting steps, items, mental counting). This behavior is often related to obsessive thoughts (e.g. counting to four to prevent harm to a loved one) but can also be done for no reason.

Social compulsions include:

- *Gambling*: Difficulty with impulse control resulting in an inability to resist the urge to gamble. Typically a chronic compulsion, although the patterns of gambling may occur during distinct episodes. Individuals will spend hours gambling, planning future gambling, and reliving past gambling experiences.
- *Shopping:* Excessive buying of items that results in financial and personal distress. Individuals will experience intrusive urges to buy as a way to neutralize feelings of increasing anxiety. Has been found to be highly associated with compulsive hoarding.
- *Hoarding*: The inability to discard belongings that appear to hold limited value. Often results in cluttered living spaces that make normal activities difficult and causes significant distress or impairment in functioning. Individuals hold on to objects for instrumental (e.g. potential utility) and sentimental reasons that are above and beyond what would be considered reasonable.

Physical compulsions include:

- *Trichotillomania:* Also known as *hair-pulling disorder* is characterized by persistent pulling out of one's own hair resulting in hair loss. Hair-pulling sites may vary over time but can occur at any place on the body. The most common sites include the scalp, eyebrows, and eyelids (APA, 2013). Hair pulling may be ongoing for an individual throughout the day or may occur during specific episodes that can last for hours at a time.
- *Sexual behaviors*: Includes compulsive masturbation, engaging in multiple sexual relationships, viewing online pornography, or participating in online chat rooms. Individuals spend hours each day fantasizing about, resisting the urge to, and/or engaging in these sexual behaviors.

Abnormal versus Normal Compulsions

Ritualistic and compulsive behaviors are a common phenomenon among healthy, normal individuals and center around the need for routine and consistency. Both healthy and clinical individuals may engage in compulsive behaviors such as checking, washing/cleaning, ordering, and avoiding particular objects. However, there is a clear distinction between abnormal and normal compulsions. Despite the similarities in content, abnormal compulsions are elicited with more frequency, intensity, and discomfort than behaviors that are considered normal. Abnormal compulsions are also more distressing and produce more negative thoughts for an individual than normal compulsions.

Compulsion and Addiction

Addiction is a disorder of the brain's reward pathways in which an individual becomes dependent on rewarding stimuli. Examples include drug or alcohol addictions, but can also be expanded to include behavioral addictions such as exercise, food, gambling, or sexual addictions. A main feature of addictions is the compulsive nature of the behavior. Individuals with addictions struggle to resist the urge to use, obtain, or engage in their rewarding stimuli. As such, it is not surprising that both individuals with addiction and individuals with compulsive behavior have difficulty with inhibition and discontinuing the harmful behaviors. While both addictions and compulsions can offer relief from stress or anxiety, addictions are typically not accompanied by the same types of obsessive thoughts as compulsions and are done for the pleasant sensations that they evoke rather than to relieve anxiety.

Impact on Individuals

Compulsions are often time-consuming (e.g. more than one hour per day) and cause significant distress or impairment to an individual's daily functioning. The impact that compulsions have on an individual may vary in terms of the degree of insight they have about the accuracy of their underlying belief. Individuals with compulsive symptoms may have *good or fair insight*, *poor insight,* or *absent insight/delusional beliefs.* Many individuals will avoid places, people, or items that could trigger obsessive thoughts or compulsive behaviors. For example, an individual may avoid using any public restrooms for fear of contamination.

Compulsions that have a childhood onset may be more or less present over the course of development and although they tend to be chronic, some children may experience remission by early adulthood. On the other hand, compulsions that have onset in adulthood tend to be more persistent and are more likely to continue into late adulthood. Compulsions also typically reflect an individual's developmental level. As such, the types of compulsions will differ slightly among children, adolescents, and adults. For example, children are less likely than adolescents or adults to display sexual behavior compulsions but will be more likely to display washing, counting, or ordering compulsions in response to anxiety about bad things happening to their parents.

Connection to Psychological Disorders

There are a number of disorders that incorporate compulsive behaviors into their diagnostic criteria, as identified by the *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (DSM-V; APA, 2013). The primary disorders that incorporate these behaviors include Obsessive-Compulsive Disorder (OCD), Autism Spectrum Disorder (ASD), Prader–Willi syndrome (PWS), Tourette's syndrome (TS), and schizophrenia.

OCD is characterized by the presence of obsessions and/or compulsions. Obsessions are repetitive and persistent thoughts, images, or urges that result in pronounced anxiety or distress (e.g. fears of contamination, excessive doubt) whereas compulsions are the actions

taken to lessen the anxiety/distress associated with the obsessions (e.g. handwashing, checking, counting).

ASD is characterized by impairment in social interaction and communication and restrictive patterns of behaviors and/or interests. Compulsions are common among individuals with ASD, and the repetitive routines and rituals that are seen in OCD are also frequent in ASD. For example, individuals with ASD will often need to follow an exact route to school each day or have family members sit in the same chairs during meals. Many individuals with ASD exhibit compulsions that are identical to those expressed by individuals with OCD.

PWS is a genetic disorder in which the deletion of the 15q11–13 chromosome results in a drive to overeat, a short stature, and hypogonadism (i.e. decreased functional activity of the gonads). Individuals with PWS often exhibit ritualistic and compulsive behaviors similar to that seen in OCD. The most commonly reported compulsions for individuals with PWS are excessive or ritualistic washing, repeating, checking, and hoarding.

TS is a neurodevelopmental disorder characterized by motor and vocal tics. Tics are often brief and repetitive movements or phonations (i.e. vocal sounds). High co-morbidity rates of up to 50% exist between TS and OCD (Swain, Scahill, Lombroso, King, & Leckman, 2007). The repetitive behaviors exhibited by individuals with TS are either without distress and in response to a strong urge or with distress and performed as a way to reduce anxiety. The most common repetitive behaviors exhibited by individuals with TS are touching, counting, symmetry rituals, checking, and washing.

Schizophrenia is a neuropsychiatric disorder characterized by disruptions in cognition, perception, and social relatedness. Individuals with schizophrenia may have positive symptoms (e.g. hallucinations, delusions, disorganized speech and behavior) and/or negative symptoms (e.g. affective flattening, avolition, anhedonia, social withdrawal). More than one third of individuals with schizophrenia display obsessive and compulsive symptoms and around 10–20% meet full criteria for OCD. The presence of obsessions and compulsions (OC) may represent a distinct subtype of schizophrenia. OC symptoms in schizophrenia are associated with poorer outcomes such as lower psychosocial functioning, increased deficits in executive functioning, and higher levels of negative symptoms (Lysaker, Bryson, Marks, Greig, & Bell, 2002).

Measuring Compulsions

The measurement of compulsion symptoms is not typically done in isolation but rather is completed within an assessment conducted for OCD. There are four commonly used methods to assessing OC symptoms including diagnostic interviews, clinician-administered inventories, self-report measures, and parent-report measures. The most commonly used clinician-rated inventory is the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS), while the most commonly used self-report measures are the Vancouver Obsessional Compulsive Inventory-Revised (VOCI-R) and the Obsessive Compulsive Inventory-Revised (OCI-R).

Treatments

Generally speaking, there are three types of treatment for compulsions: psychotherapy, pharmacotherapy, and brain modulation. Psychotherapy, in particular exposure and response prevention (ERP), is recommended as the first-line treatment option for reducing compulsive symptoms (Van Balkom et al., 1994). ERP consists of repeated and prolonged exposure to fear-eliciting stimuli or situation (e.g. walking into a public bathroom). During ERP, therapists instruct the patient to refrain from engaging in the compulsive behavior as a way to reduce their anxiety. For example, if the patient has a fear related to contamination, the therapist may ask the patient to refrain from washing their hands after touching a toilet seat. The purpose is to allow the patient to experience anxiety reduction naturally without engaging in behaviors to avoid it. 60–85% of patients report reduction of their symptoms through the use of ERP, with maintenance of results for up to five years after discontinuation of the treatment. ERP and behavioral therapies work best for overt compulsive behaviors (e.g. hand washing) but are more difficult for more covert types of compulsive behaviors (e.g. mental counting) (Rachman, 1997).

Pharmacotherapy or medication intervention includes the use of selective serotonin reuptake inhibitors (SSRIs) or tricyclic antidepressants such as clomipramine. Pharmacotherapy often works best when used in combination with psychotherapy, especially for individuals who may be too frightened by the exposure therapy. In this case, pharmacotherapy should first be started in order to reduce symptoms and then therapists may begin with the ERP.

Brain modulation, or deep brain stimulation (DBS), is considered in patients who suffer with severe OCD that has not responded to an adequate number or sessions of psychotherapy or pharmacotherapy. DBS is a procedure in which high-frequency electrical impulses are sent to specific parts of the brain to break the cycle of the compulsive behavioral patterns. The research on DBS is promising; however, it is currently still considered an experimental approach.

Overall, although many therapies show reduction of compulsive symptoms, it is challenging to completely cure compulsions. After completing ERP, patients' symptoms often demonstrate significant improvement; however, these individuals still reported higher levels of compulsive symptoms than the general population, suggesting that symptoms did not completely resolve (Abramowitz, 1998).

Coping

James D. A. Parker[1] and Gabriela Sheinin[2]

[1] *Trent University, Ontario*
[2] *University of Windsor*

People's responses to stressful situations continue to be studied extensively in the psychological literature. There is a long history connected to understanding how people "cope" with negative events, which begins in the late nineteenth century with Freud's early psychoanalytic concept of "defence mechanisms" (Parker & Endler, 1996). The study of the implications of various defenses became a major research area for much of the twentieth century. Beginning in the 1960s, however, researchers began to identify some adaptive responses toward stressful and harmful situations as "coping" behaviors. Since that time, researchers have continued to study the various aspects of coping and how it can be assessed, as well as how coping predicts a variety of life-success and wellness outcomes.

The origins of the concept of coping were in the late nineteenth century, among the works of Freud and his early writings on psychoanalysis. Freud observed that it is possible for traumatic thoughts to exist exclusively in the unconscious (Freud, 1955). In order to defend themselves, Freud suggested that individuals used various strategies meant to repress, change, or keep away harmful thoughts. Over the course of his writings he identified and described a number of "defense mechanisms": regression, repression, reversal, sublimation, introjection, projection, reaction formation, solation undoing, and turning against the self. Though repression and defense had previously been viewed as equivalent terms, Freud eventually characterized defense as the method that the ego uses in order to defend against harmful thoughts and feelings. Repression was subsequently defined by Freud as just one of several types of defense mechanisms.

Anna Freud also contributed substantially to the development of the modern concept of coping. In Anna Freud's work, "The Ego and the Mechanisms of Defense" (Freud, 1946), not only did she consolidate her father's various ideas about defense mechanisms, but she also described and defined several new defenses: identification with the aggressor, ego restriction, denial in fantasy, intellectualization, and altruistic surrender. In addition to cataloging core defense mechanisms, Anna Freud also promoted the idea that each individual has a set of preferred defenses – a precursor to the idea of "defense styles." She also

promoted the idea that certain defense mechanisms have the potential to be less pathological than others. This position led others to introduce models of adaptive versus non-adaptive defenses, as well as models that suggested that defenses can be organized in a hierarchy according to their levels of psychopathology and/or wellness.

Three main approaches were developed to assess defense mechanisms: observer-reports, self-report, and projective techniques (Parker & Endler, 1996). One of the first observer-rated assessments to identify defense mechanisms consisted of 20 definitions for ego mechanisms: 10 definitions for defense mechanisms and 10 definitions for coping mechanisms (Haan, 1963). This assessment strategy quickly led to the development of various other assessment tools. Of particular note is the work conducted by Vaillant (1971). His assessment technique for defense mechanisms was unique in that it sought to assess how people reacted in different stressful situations. Vaillant's general findings were consistent with a hierarchical defense model, as he found evidence that mature defenses were typical of positive adult adjustment, while immature defenses indicated poor adjustment (Vaillant, 1977).

Beginning in the 1960s, there were also considerable efforts made to develop self-report measures for various defense mechanism constructs. Haan (1965) created one of the first self-report measures by adapting items from the *Minnesota Multiphasic Personality Inventory* and the *California Personality Inventory* to create nine coping mechanism scales and seven defense mechanism scales. Another influential self-report measure in the literature (Parker & Endler, 1996) was the *Defense Style Questionnaire* (*DSQ*), developed initially to assess four distinct dimensions: immature defenses, adaptive defenses, image-distorting defenses, and self-sacrificing defenses. This assessment tool was later modified to assess a three-dimensional model widely adopted in the literature: mature defense, neurotic defense, and immature defense.

In the 1960s, the concept of coping evolved in the psychological literature from being used casually to becoming a technical term for adaptive defense mechanisms. By the early 1970s, the concept of coping had begun to be differentiated from defense mechanisms. Coping became identified with behaviors characterized as flexible, with purpose, and realistic. Eventually, coping responses evolved into an independent area of research that focused on conscious behaviors for dealing with upsetting and stressful situations. The first cohort of "coping" researchers distinguished emotion-focused coping and problem-focused coping as two important types of responses, and these two broad strategies continue to be relevant to the present day. Emotion-focused coping involves methods such as fantasy and other forms of self-involvement that relate to the regulation of one's emotions. In comparison, problem-focused coping involves resolving or reducing the effects of a stressful situation. Another dimension of coping research that was identified early on, avoidance-oriented coping, also continues to be one of the key coping dimensions in contemporary research. This type of coping encourages individuals to distract themselves from stressful situations in various ways.

It should be noted that in the early coping area researchers focused exclusively on the study of reactions to life-threatening and traumatic situations. This early trend from the late 1960s was very influential in shaping influential conceptual models for the coping construct. Although later generations of coping researchers would eventually come to study a broad range of situations, the initial trend of studying traumatic-like situations had the effect of limiting interest in dispositional or stable trait-like coping constructs

(Parker & Endler, 1996). Of course the history of the coping area at this time also mirrors events going on in personality psychology in general from the 1960s to the 1980s, where the trait approach was seriously challenged by situationism.

As with developments in other areas of psychology, interest in traits became widespread once again in the coping area in the late 1980s. More specifically, coping researchers began to explicitly acknowledge a distinction between an "interindividual" and "intraindividual" approach to coping (Folkman & Lazarus, 1985). The intraindividual approach seeks to identify basic coping strategies used by people in specific stressful situations. The interindividual approach, on the other hand, attempts to identify habitual coping strategies used by people across different types of stressful situations.

Similar to the research with defense mechanisms, coping researchers have developed a variety of ways in which to assess coping behaviors (Parker & Endler, 1996). Coping measures can be categorized based on tools developed following "interindividual" or "intraindividual" approaches. For the latter, a number of situation-specific tools have been developed, in which coping behaviors in specific stressful situations are assessed. Stressful situations such as illness and other health-related factors have often been used to develop these measures. As a result, the relationship between coping and health has been a popular area of research. One model, which is used most often in coping and health research, suggests that coping behaviors directly affect physical health; other models suggest that coping strategies influence aspects of one's health indirectly through behaviors such as regularly seeing health care professionals.

The *Ways of Coping Checklist* (*WCC*; Folkman & Lazarus, 1980) later revised as the *Ways of Coping Questionnaire* (*WCQ*; Folkman & Lazarus, 1988) has had the most influence of intraindividual coping measures in the area. Not only has this tool been used in many studies, but it has also become a key validating variable in the development of other coping measures. The original *WCC* was a self-report measure with 68 yes/no questions designed to assess problem-focused coping and emotion-focused coping. Folkman and Lazarus (1988) subsequently modified the scale (renaming it as the *WCQ*) to have 66 items rated on 4-point Likert scales. Although the measure continues to be widely used in the field, a number of psychometric short-comings have never been resolved. For example, many researchers have had problems replicating the factor structure for the tool, and it remains unclear how reliable the coping scales are over different time-frames (Parker & Endler, 1996).

In contrast to assessment tools like the *WCQ*, interindividual coping measures continue to be more controversial in the coping community (Parker & Endler, 1996). Many researchers argue that predispositions are not indicative of how individuals react in stressful situations; however, beginning in the late 1980s, some researchers began to look for evidence of coping styles. One of the earliest of these assessment tools was the *COPE Inventory* developed by Carver, Scheier, and Weintraub (1989). This self-report measure has five scales that measure different aspects of problem-focused coping (active coping, planning, suppression of competing activities, restraint coping, and seeking of instrumental social support) and five scales that measure different aspects of emotion-focused coping (seeking of emotional social support, positive reinterpretation, acceptance, denial, and turning to religion). The *COPE* also has three other scales that measure different non-adaptive coping strategies (venting of emotions, behavioral disengagement, and mental disengagement). The *COPE* remains the most widely used measure in the coping area.

The concept of coping has a long history in which it evolved from Freud's theory of defense mechanisms to become a conceptually distinct research area. Although the coping and defense mechanism literature utilizes similar measurement strategies (e.g. self-report tools) and sought to predict similar life-success and wellness outcome variables, the two areas have grown into two very independent fields. Within the coping area of the last three decades, two broad trends can be identified: the distinction between interindividual and intraindividual conceptual models, with their concomitant sets of assessment tools, as well as the focus on two broad coping strategies that transcend the two conceptual approaches – problem-focused coping and emotion-focused coping.

Core Self-Evaluation

Annamaria Di Fabio and Letizia Palazzeschi

University of Florence, Italy

Definition of Core Self-Evaluation

Core self-evaluation can be defined as positive self-concept in terms of self-esteem, general self-efficacy, absence of pessimism, locus of control (Judge, Erez, Bono, & Thoresen, 2003; Judge, Locke, & Durham, 1997). In particular it is a higher order construct that includes these four specific constructs. Self-esteem is considered the overall value that the person ascribes to herself/himself; general self-efficacy is relative to the perceived evaluation of one's own capacity to adequately perform in different settings; absence of pessimism is defined as the tendency to have a positive explanatory style and to consider one's own resources; locus of control refers specifically to intern locus of control that is the attribution of causality of events to the person and not to external causes. Core self-evaluation was initially developed to find individual characteristics that can explain job performance in organizations (Judge et al., 1997). The four constructs that composed the higher order construct of core self-evaluation were chosen on the basis of the following three criteria: evaluation-focus, fundamentality, scope. Specifically, evaluation-focus criterion refers to the evaluation of individual characteristics rather than a simple description; fundamentality refers to characteristics that are more central to one's self-concept; scope refers to how broad or specific the characteristic is. The four constructs included in the core self-evaluation construct represents in fact evaluations of broad individual characteristics, referring to aspects that are more fundamental for individual and more central to one's self-concept.

Measurement of Core Self-Evaluation

Regarding the measure of the core self-evaluation construct, Judge et al. (2003) have first developed a set of 65 items based on the literature on measures of the four components (self-esteem, example of item "Overall, I am satisfied with myself"; general self-efficacy, example of item, "I complete tasks successfully"; absence of pessimism, example of item

"I am capable of coping with most of my problems"; locus of control example of item, "I determine what will happen in my life") of the core self-evaluation construct. From this initial group of items, they have identified 12 items corresponding to the four components. Among these items, six were formulated in a positive manner and six in a negative manner. These 12 items constitute the Core Self-Evaluation Scale (CSES) whose answer modality is on a 5-point Likert scale (1 = *strongly disagree* to 5 = *strongly agree*). The authors found high levels of internal consistency and good reliability. Confirmatory factor analysis confirmed that the items of CSES are indicators of a single latent high order construct.

The Core Self-Evaluation Scale was adapted and validated in different international contexts such as Italian, German, and Iranian contexts.

Similarity and Differences of Core Self-Evaluation to Other Constructs

The discriminant validity of core self-evaluation was studied in relation to other similar constructs to analyze if the core self-evaluation presents some similarities with the other constructs or if it represents a distinct construct. The core self-evaluation was studied in particular in comparison with the Five-Factor model. Core self-evaluation explains a percentage of incremental variance over personality traits in relation to job satisfaction, job performance, life satisfaction (Judge et al., 2003). These results show that core self-evaluation and personality traits are different constructs. Some authors argued that the neuroticism of the Big Five model can overlap with core self-evaluation. If it can be true that the definition of neuroticism of the Big Five model includes some aspects relative to the presence of pessimism as a tendency to have a negativistic explanatory style, neuroticism does not refer to self-esteem, self-efficacy, and locus of control. Moreover, Big Five traits are relative to descriptive characteristics of individuals whereas core self-evaluation includes an evaluative component. The core self-evaluation was also studied in comparison with positive/negative affectivity, showing that core self-evaluation is linked to job and life satisfaction (Heller, Judge, & Watson, 2002). These results also showed that core self-evaluation and positive/negative affectivity are different constructs, highlighting that the affective component is not part of the core self-evaluation construct (Heller et al., 2002).

Explanations of Core Self-Evaluation and Important Outcomes

The research regarding explanation of core self-evaluation is not particularly widespread. However, an interesting perspective concerns a genetic explanation of core self-evaluation (Judge, Ilies, & Zhang, 2012). The heritability of core self-evaluation is shown in the studies on twins. Several studies have also supported the genetic basis of some of the individual core characteristics, such as absence of pessimism and self-esteem. Furthermore it is possible to distinguish different processes that shape how core self-evaluation characteristics are manifested. Generalized self-efficacy and locus of control are respectively cognitive appraisals about oneself and the environment. These appraisals are influenced by successful and unsuccessful prior attempts at exercising control over one's behavior and context.

Self-esteem regards fundamental beliefs about one's self, shaped by self-worth and other self-relevant information, also at symbolic levels. At a physiological level, these evaluation processes are located at the level of cerebral cortex and they have a strong cognitive component. Instead absence of pessimism is more characterized by an emotional component. In particular, absence of pessimism is associated with a lack of avoidance-oriented motivation and negative affect along an anxious-calm continuum. Avoidance motivation and its corresponding negative affect are processed in primitive physiological and emotion-based cognitive architectures of the amygdala and limbic system. Core self-evaluation characteristics therefore differ in the types of information processing and neural systems that regard them.

If research of explanation of core self-evaluation was limited, the studies on core self-evaluation were mainly relative to its outcomes. The construct of core self-evaluation was traditionally studied above all in the organizational field particularly in relation to job satisfaction and job performance. Positive relations consistently emerged between core self-evaluation and job satisfaction. Research showed the relations between core self-evaluation and job satisfaction, underlining the fact that workers who evaluate themselves in a more positive way seem more satisfied with their job. Core self-evaluation is traditionally associated also with job performance, suggesting that workers with a higher core self-evaluation are more confident to be able to perform well and for this reason they are more motivated in their work, performing well.

In organizational contexts, core self-evaluation was studied in relation to other variables such as job stress, job burnout, economic success. Regarding the relation between core self-evaluation and job stress, workers who evaluate themselves in a positive way seem more able to face stressful situations in the workplace, perceiving less job stress. Concerning the relation between core self-evaluation and job burnout, individuals with high core self-evaluation seem to perceive themselves as more able to manage difficult situations in the workplace, experiencing less job burnout. With regard to economic success, core self-evaluation was longitudinally studied in relation to income level when participants are young adults and then in their mid-life, showing that core self-evaluation has a positive relation with income level over time. More recently research also shows that core self-evaluation was positively associated with more positive judgment of team effectiveness that contributes to increase performance management team behavior. High core self-evaluation of both followers and leaders is related more to followers' role clarity that increases leader-member interactions. Furthermore, high core self-evaluation enhances team social interactions that consequently improves team effectiveness.

Further variables associated with core self-evaluation are life satisfaction and psychological distress. Individuals with high core self-evaluation perceive a greater general satisfaction with their lives and lower psychological distress. High core self-evaluation is also associated with low emotional exhaustion and low cynicism that are both associated with job satisfaction.

Recently in the vocational field there is an increasing interest in the core self-evaluation construct. Core self-evaluation is positively associated with vocational identity in terms of commitment and exploration of individual identity as a worker that is in turn associated with life satisfaction. Furthermore, research underlines the contribution of core self-evaluation in decision-making processes, showing relations between core self-evaluation and decisional variables such as career decision-making difficulties, decisional styles and indecisiveness.

Particularly core self-evaluation was related to different kind of career decision-making difficulties such as lack of readiness, lack of information, and inconsistent information. Core self-evaluation showed correlations with adaptive decisional style vigilance and with inadequate decisional styles, particularly with hyper-vigilance. Furthermore among decisional aspects, core self-evaluation is especially related to indecisiveness.

core self-evaluation constitutes a promising variable since it is associated with many different outcomes relative to the organizational field, the well-being of individuals, and more recently to vocational fields.

Dealing with Core Self-Evaluation

Since core self-evaluation results are associated with many different outcomes, it is important to enhance core self-evaluation with specific training. This training to enhance core self-evaluation is focused on the increase of four specific constructs (self-esteem, self-efficacy, absence of pessimism, locus of control) that are included in this higher order construct. Training to enhance self-esteem is focused on identifying successful experience in one's own life, producing positive affirmation on oneself, and use self-appreciation techniques. Training to enhance self-efficacy are centered on identifying positive results in one's own life, clarifying the sequence of actions useful to reach such positive results; identifying one's own strengths; clearly identifying one's own objective and focusing on the possibility to achieve these objectives; engaging with perseverance and constancy in new, stimulating, diversified, and tasks increasing in difficulty. Training regarding absence of pessimism refers to counteracting negative thoughts turning them into positive affirmations; monitoring one's own internal dialogue, noting the thoughts that arise when facing difficulties; remembering to not think negatively when faced with adversities to prevent negative thoughts; facing with negative thoughts and bringing evidence in support of such thoughts and evidence to refute these thoughts and implement subsequent reflection. Training to increase internal locus of control is relative to exercises focused on the fact that there is always a way for individuals to personally change negative situations; on the opportunity to individuate possible actions when there seems to be no possibility of choice; on the strengthening of problem-solving of individuals.

Particularly in the guidance and career counseling field, it has recently emerged that dialogue interventions such as "Constructing my future Purposeful Life" (Di Fabio, 2014) increase core self-evaluation in terms of development of greater positive self-concept after the dialogue intervention in relation to the process of reflexivity and of greater awareness of one's own identity.

Creativity

Maria-Jose Sanchez-Ruiz

Lebanese American University

The Conceptualization of Creativity

Creativity is an intriguing and complex construct that has been studied for centuries because of its undeniable importance for humankind's progress. There are multiple conceptualizations of creativity, but the most accepted one defines the construct as the way of thinking that results in products that have both novelty and utility (i.e. are valuable and effective). Despite its recognized value, this *new and useful* conceptualization of creativity is limited to the creativity output and might be unable to discriminate among creative products. Creativity definitions have traditionally been grouped into four areas of research: the creative *person*, the creative *process*, the *environmental* conditions in which creativity occurs, and the *product* resulting from creative activity. Integrative definitions of creativity recognize the multifaceted nature of the construct and the interaction among the above-mentioned areas.

Even though tremendous efforts have been made in proposing integrative models, there is still need for a solid framework to incorporate the vast and diverse research evidence. The disparity of findings is partly due to the multiple approaches and measures used to assess creativity (e.g. divergent thinking [DT] tests, personality inventories, creative behavior checklists, external evaluations, etc.) which has compromised the comparability of research findings. Some promising attempts to simultaneously assess the multiple creativity components (e.g. cognition, emotion, and motivation) have been recently proposed. New heuristic frameworks have suggested three dimensions to classify creativity measures, namely the *level* or unit of analysis (e.g. the individual or the team), the *facet* or what is being assessed (person, process, environment, or product), and the *measurement approach* (e.g. objective or self-report; Batey, 2012).

Individual Differences in Creativity

Research on the creative *person* has tried to differentiate between a creative individual and a non-creative one for decades. Three main factors have been identified to contribute to creativity, namely environmental/demographic variables, cognitive abilities and personality traits. There are contradictory findings on the role of gender in creativity; however, evidence shows that females outperform males on verbal measures and the opposite is true for figural/numerical measures of creativity. Creativity peaks during middle adulthood and declines as individuals grow older. Also, high levels of education and socio-economic status are often linked to higher creativity. The bulk of research has focused on the other two areas; cognitive abilities (mainly intelligence) and personality traits. Affective traits and states have also been shown to influence creativity.

Creativity and Intelligence

The study of individual differences in creativity originated in early research on intelligence. In fact, creativity was initially considered a subset of intelligence, linked to fluid intelligence (Gf). However, traditional intelligence tests could not comprehensively measure creativity, despite some of them considering fluency as a component of intelligence. The first DT tests assessed fluency, flexibility, and originality. Since then, they have been widely used to assess creativity, even though they are not exempt from criticisms (e.g. lack of predictive validity). Studies exploring creativity (mainly using DT tests) and intelligence (mainly using IQ tests) have generally shown moderate to weak associations between the two, thus supporting the idea that they are independent constructs.

The well-established threshold theory assumes a cut-off in IQ (i.e. 120 points) beyond which creativity is no longer related to intelligence. However, studies differ in their reported thresholds and direction of relation, which might depend on the operationalization of creativity and the sample used. In addition, some cognitive abilities seem to relate to creativity differentially across domains. For example, while verbal ability might be more relevant for individuals in specific art disciplines, problem-solving skills are more prominent in the sciences field.

Research suggests that intelligence contributes to creative performance but is insufficient for creative achievement. Non-cognitive factors such as personality, affective dispositions, and environment are equally if not more important for creative achievement.

Creativity and Personality

Early meta-analytic data characterized creative individuals as open to experiences, autonomous, unconventional, self-confident, dominant, ambitious, and impulsive. Psychoticism (from the Gigantic 3 model) has been linked to creativity through unusual ideation, over-inclusive thinking, and remote associations. Such links have been supported by considerable clinical, subclinical, and non-clinical evidence from individuals with schizotypy features.

Studies adopting the Five Factor Model of personality report a strong and consistent relation between creativity and openness to experience, which affords a vivid imagination, artistic tendencies, unconventionality, preference for challenges, and curiosity, all of which facilitate creative endeavor. Extraversion has been shown to be relevant for creativity

within particular domains (e.g. business). There seems to be a weak negative relationship between agreeableness and creativity, and the rest of the factors have domain-specific relationships with creativity. For example, conscientiousness and emotional stability support creativity in sciences but hamper it in arts.

Other research contends that creative individuals have *complex personalities*, with traits operating at both ends of the dimension (e.g. imaginative and realistic), which facilitates creativity depending on the situation. Recently, some researchers have argued that approach-related traits (e.g. extraversion and openness to experience) are linked to higher cognitive flexibility and thus relate to divergent thinking styles, while avoidant-related traits (e.g. conscientiousness and neuroticism) facilitate convergent thinking as they are associated with cognitive perseverance.

Recent integrative models on the relationship between personality and creativity, such as the functional model of the creative personality (Feist, 2010), suggest that cognitive-related (e.g. openness to experience), social (e.g. nonconformity), affective-motivational (e.g. intrinsic motivation) and clinical (e.g. psychoticism) traits influence creativity through the interaction of biological and behavioral dispositions. Another multicomponential model is Furst, Ghisletta, and Lubart's (2014), whereby personality factors, namely plasticity (e.g. high openness to experience and extraversion), divergence (e.g. low agreeableness and conscientiousness), and convergence (high ambition and precision), interact to promote creativity and influence the creative *process*. These models are promising but need empirical support and further recognition of environmental factors.

Creativity and Emotions

Research is not as extensive regarding individual differences in the affective parts of the personality realm. There are currently two main streams of research exploring creativity and emotions: affect-related traits or states. Some research studying creativity and emotions as traits has adopted the *trait emotional-intelligence* (*trait EI* or *trait emotional self-efficacy*) model, which covers a wide range of emotion-related dispositions. Certain trait EI dimensions such as sociability are associated with creativity, while emotionality and low self-control were linked to creativity in arts, but neither in sciences nor social sciences.

Another body of research examines the impact of the valence and activation of positive and negative moods on creativity. One of the most relevant contributions in this regard is the dual pathway model (de Dreu, Bass, & Nijstad, 2008), which maintains that both positive and negative moods can facilitate creativity through different routes. While the former promotes optimism in the face of challenge and thus enhances flexibility, the latter optimizes efforts and promotes determination, exploration, which results in increased fluency. The same model argues that positive moods (e.g. happiness) enhance fluency and originality, in contrast to deactivating moods (e.g. sadness) that can lower the motivation to act creatively.

The Creative Brain

Research evidence indicates that creativity studies have explored the neurophysiology and show structural and functional correlates of creativity. Regarding the former, lesion studies show that fronto-temporal damage facilitate artistic creativity (possibly through a disinhibitory impact)

while parietal damage can hinder it. Overall, these studies show that the fronto-lateral portion of the frontal lobe has a significant role in the generation of new and useful ideas.

Increased gray matter thickness in the right posterior cingulate gyrus and right angular gyrus was associated with creative achievement and performance, respectively. Decreased cortical thickness in other areas (e.g. left frontal lobe) also predicted creativity. Moreover, gray matter tissue volume in the right superior parietal lobe was positively associated with DT scores, while white matter pathways facilitated the "efficient integration of information" that is essential for idea generation. In fact, connectivity and increased structural integrity in the frontal lobe and corpus callosum have been correlated with higher creativity scores.

Structural neuroimaging research has suggested that in order to understand the neuro-biological underpinnings of creative cognition, research can investigate the network connections in the brain and the hubs (highly connected and central brain regions) instead of attempting to localize brain areas for specific creative processes.

As for functional imaging studies, electroencephalographic (EEG) data is mixed, but a general trend shows amplitude and synchronization changes in the alpha-band are associated with creative performance. Findings from fMRI studies are also difficult to interpret, but the trend shows activation of the frontal, temporal, and limbic lobes during creative activity (see Arden, Chavez, Grazioplene, & Jung, 2010 for a review).

Neuroscientific findings so far are promising but difficult to integrate, mainly due to the different creativity and neuroimaging measures used across studies. Research is needed using multimodal designs and creative tasks that resemble reality as closely as possible, while attempting to control the effect of the imaging techniques on participants to reach unbiased results.

The Creative Environment

Current studies investigate not only the creative individuals, but also their environment. One important area of study is how cognitive processes, personality attributes, and working/studying approaches that differ across domains (e.g. sciences, arts) influence creativity.

Another area is the creative climate, or perceived situational elements that facilitate creativity, which is generally studied within organizational settings, and refers to dimensions such as support and autonomy. Other factors contributing to the creative climate are work-group support, challenge, and involvement, organizational reinforcers and impediments, autonomy, workload, idea time and support, flexibility and risk-taking (see Hunter, Bedell, & Mumford, 2007 for a review). These elements might interact with personality variables to facilitate creativity, understood in the organizational context as the generation of new ideas, which in turn leads to innovation, the application of such ideas to reach new and useful outcomes. Innovation is ultimately linked to higher productivity and socio-economic growth.

However, more work is needed on the differential predictive value of the creative climate elements, their assessment, and mediation/moderation effect of other variables. For example, studies show that employees' work motivation mediates the relationship between creativity climate and perceived innovation.

Future research on creativity can pioneer approaches that adopt a global view to better understand how nature and nurture interactions affect creativity. There is a need for a

conceptual and assessment framework of creativity. This framework can serve as a tool for needs assessment and monitoring the development of creativity programs aiming at fostering creative thinking among individuals and across diverse domains.

Culture and Personality

David B. Mykota

University of Saskatchewan

Background

During the early twentieth century culture and personality became a focus of study. At this time, culture and personality studies were influenced by both anthropology and sociology and were the precursor to cross-cultural psychology and research on personality. From their inception, culture and personality studies undertook an interdisciplinary approach integrating the fields of anthropology, sociology, and psychology.

Anthropologists Edward Sapir, Margret Mead (i.e. *Coming of Age in Samoa*) and Ruth Benedict (i.e. *Patterns of Culture*) along with sociologists Ernest Burgess and William Thomas were seminal thinkers in the field and initiated discussion on the relationship between personality, society, and culture. It was during the 1930s that the Social Science Research Council (SSRC) established an advisory committee, which has been credited with the establishment of personality and culture, as a distinct field of study. At this time, Sapir was invited to chair the SSRC Hanover Conference in which he argued that a simple application of Jung's early work on personality classification (i.e. rational vs. irrational and introvert vs. extravert) need be understood within the context of cultural (social) norms and that whole cultures could be interpreted within this framework.

Although the field flourished during the 1930s, it declined in popularity after WW II. This was in part because culture and personality studies were characterized by attempts to ascribe national personality characteristics to nation states (i.e. Germany and Japan). However, as these studies were found lacking in empirical validity, the field waned and its popularity declined. It was during this time that the relativist school of thought dominated the field. From the relativist perspective, culture was viewed as the personality of a society. The relativist school of thought believed that individuals living in the same culture are socialized in a similar manner leading to personality traits specific to their culture. It is the primary institutions of the culture that aid in forming the basis of personality through socialization practices, which forms the basic personality structure of a population.

Structural Universalists: Trait Psychology

In contrast, the structural universalist school of thought, also known as trait psychology, contends that specific personality traits are predictable across cultures. Development and use of large-scale personality assessment instruments led to the popularization of the belief that dimensions of personality are consistent across cultures. The study of traits with large-scale personality assessment instrumentation using factor analysis has demonstrated considerable consistency in articulating a five-factor model of personality and in part has led to the revival of culture and personality studies (McCrae, 2000).

Nevertheless, there is disagreement as to how many dimensions encompass the "universal model." Some have proposed a six-factor model that comprises an additional honesty-humility factor, while others who use language as the basis for the exploration of personality traits across cultures have concluded that that only three dimensions (extraversion, agreeableness, and conscientiousness) can be replicated across cultures.

Owing to the overreliance of self-report instruments on the measurement of personality, criticisms were also related to the susceptibility of respondents toward social desirability in their response patterns. Among cross-cultural psychologists, it is argued that there is a preponderance of Western methods in the research undertaken to the understanding of cultural universals. In this respect, methodological issues (i.e. the lack of indigenous constructs) and item biases have also been reported which puts into question the predictive validity of the structural universalist approach.

Nonetheless, there is a growing body of empirical research that makes it difficult if not impossible to ignore the universality of personality traits across cultures. Consequently, there is an emerging consensus among cross-cultural psychologists that dispositional traits, as articulated in the five-factor model, are biologically based and therefore not cultural constructs. Rather, distinctive personality traits are interpreted as selected characteristic adaptations that are unique expressions within a given culture.

Estimates of trait differences across cultures using quantitative analysis to determine between culture variance and between person variance have demonstrated relative stability in interpreting personality traits across cultures when data sets from self-report measures of personality are used. However, the samples are mainly drawn from literate Western societies and this is viewed as a major limitation in interpreting the research findings and ascribing universal patterns to personality across cultures.

Perspectives Among Psychologists

Evolutionary psychologists focus on the relationship between the environment and evolved psychological process. They do not view culture as a mechanism which influences personality; rather human psychological processes in interaction with the environment cause species to adapt, which results in differences (i.e. personality) to exist. Evolutionary psychologists do not believe then that cultural variables are the causal agent in personality development. Instead of an evolutionary perspective it is the adaptation of "psychological mechanisms" (i.e. personality) to the environment that causes cultural differences to evolve.

Indigenous psychologists use a more relativistic approach in the understanding of individual differences. Accordingly, there is a growing body of research among Indigenous psychologists who are attempting to validate personality constructs unique to a particular cultural milieu. Consequently, much of the work undertaken by Indigenous psychologists in the exploration of personality within a culture is ethnographic in nature.

Limitations of such an approach are found in the lack of evidence available that confirms the cultural features that permeate personality constructs of a specific culture that can be described as basic heritable tendencies within a culture. Thus it is argued that there is little support for confirming indigenous constructs as being culturally unique as opposed to culturally relevant expressions of the major personality dimensions as articulated by cross-cultural researchers.

Like Indigenous psychologists, cultural psychologists take a relativistic point of view. Cultural psychologists ascribe to the viewpoint that personality traits are constructed socially and therefore unique to a specific culture. Research by cultural psychologists tends to be conducted in non-Western cultures in an attempt to deemphasize the dispositional trait approach advocated by the structural universalists. In contrast, studies undertaken by cultural psychologists employ a constructivist approach, which articulates cultural influences on personality. The methods used by cultural psychologists are characterized by ethnographic and narrative approaches in an attempt to demonstrate contextual descriptions of cultural meaning to adaptations and their influence on personality in differing environs. Unfortunately, a major limitation of research on personality among cultural psychologists is that it has mainly occurred in a selected few cultural contexts (i.e. Asia and North America).

Emic and Etic Approaches

The various perspectives offered add to the extant research on culture and personality studies. As alluded to, these approaches can be described as occurring along a continuum favoring either a relativist or structural universalist viewpoint. Another way of articulating this distinction, that has more recently come to characterize investigations into culture and personality, is the conceptualization of the research paradigms as being either emic, which refers to culture-specific personality traits, or etic, which are those traits generalized across cultures (Poortinga & Van Hemert, 2001). This way of understanding originally evolved out of culture and language studies undertaken in the 1960s and has been applied to investigations on culture and personality.

The emic approach explores Indigenous psychological phenomena (i.e. personality) and the extent to which it is related to the culture in question. The emphasis is on the singular culture and the cultural context of the psychological processes, the relativist tradition. The etic approach attempts to understand behavior and relationships across cultures so as to delineate universal patterns of behavior (i.e. personality), much like the structural universalist paradigm advocates. Etic inquiries espouse Western research traditions and the utility of Western models and positivistic methods in the study of culture and personality. Consequently, etic studies are mainly concerned with the trait approach to the understanding of culture and personality.

It is not argued that one approach is more favorable than the other when conducting research into culture and personality. Rather, it should be remembered that both have benefits and limitations, and the whole emic–etic distinction is best viewed along a continuum. Instead of dichotomizing the two, a series of theoretical methods has emerged to advance studies on culture and personality (Poortinga & Van Hemert, 2001). This third synthesized approach to bridging research methods involving emics and etics has come to characterize recent culture and personality studies and includes the combined emic–etic approach, the integrated emic–etic approach, and the demarcated emic–etic approach. It is important to note that these methodological procedures are not specific to culture and personality studies in themselves but also include research on constructs in different cultures.

Briefly, the combined emic–etic approach can only happen when researchers agree on the importance of both the emic and etic methods when conducting research into culture and personality. This requires an understanding of the theoretical and methodological issues of both traditions. Personality differences would be described as emic in nature whereas similarities would be characterized as etic. Neither approach would supersede or take precedence over the other, rather by using a combined approach would require that there is agreement among researchers from differing traditions on how to conduct culture and personality research. Nonetheless, this approach holds promise for the understanding of culture-specific representations of personality. Limitations are found in the process of uncovering a comprehensive nomological network of the constructs that can be universally applied.

The integrated emic–etic approach is an emerging field of study in culture and personality research. Although it might be viewed as a superior method, it would require agreement among the dominant research paradigms (i.e. Indigenous and structural universalists). Even though future research might take this direction, the integration of methodological and theoretical perspectives can only occur when there is a preexisting intent on the part the researchers to integrate both traditions and there is agreement that both perspectives can contribute to the research undertaken.

The demarcated emic–etic approach recognizes that the two traditions are incompatible and that any attempt at either the combined approach or integrated approach is not tenable. What this translates into is that some personality traits are best understood as universal (i.e. emic) while others are culturally unique (i.e. etic). The demarcation approach would require agreement among researchers to delineate which consequence on any specific occasion in any cultural context is likely to occur and therefore take precedence over the other (i.e. which traits are specific to a culture). Limitations to this approach are found in assigning predictability to a specific behavioral event either as a culturally general or culturally specific occurrence and articulating with assurance, which would have greater predictive validity over the other.

Future Research

What is important for purposes of understanding future research on culture and personality, whether it be from the major traditions articulated (i.e. relativist or structural universalist), through a synthesized approach to conceptualizing emics and etics as applied to

culture and personality studies or from the perspective of Indigenous, cross-cultural or cultural psychologists, is an understanding of what facet of personality is being discussed. Within this context, the influence of culture on the various aspects of personality might differ depending upon whether one is studying dispositional traits, characteristic adaptations, or life narratives. A clear understanding of what features of personality are universal and therefore common and predictable and those that are unique, unpredictable and culture-specific needs be considered. To achieve this, it is advocated that future research embark on either an integrated or demarcated methodological approach respective of the traditions espoused by Indigenous, cross-cultural, and cultural psychologists in the study of personality and culture so that a clearer picture formulated.

Dark Triad

Rachel A. Plouffe, Claire A. Wilson, and Martin M. Smith

University of Western Ontario

Overview

The Dark Triad refers to three socially aversive traits: psychopathy, narcissism, and Machiavellianism. While psychopathy, narcissism, and Machiavellianism have meaningful factor-specific variance, they also overlap considerably. Specifically, each of the three Dark Triad traits encompasses a tendency to be callous, manipulative, and low in honesty-humility. Traditionally, researchers studied psychopathy and narcissism in clinical populations. However, psychopathy and narcissism have recently been reconceptualized as subclinical traits applicable to the general population.

Subclinical psychopathy refers to the dispositional tendency to be impulsive, thrill-seeking, erratic, and show a consistent lack of anxiety and empathy. Subclinical narcissism refers to the dispositional tendency to seek attention, fantasize of unlimited power, and possess a grandiose sense of entitlement. Finally, Machiavellianism refers to the dispositional tendency to be deceptive, manipulative, and cynical of human nature.

The importance of research pertaining to the Dark Triad is substantiated by the Dark Triad's ability to predict a number of important outcome variables (e.g. preferences for short-term mating strategies, desire for power, academic dishonesty, engagement in risk-taking behaviors, and sensation seeking). However, whether the Dark Triad consists of independent traits or a single unified construct is debated. Those who favor the "unification perspective" contend that due to psychopathy, narcissism, and Machiavellianism's overlap, all three traits fall into the same interpersonal circumplex defined by high agency and low communion. In contrast, those who favor the "uniqueness perspective" contend that a merge of the three traits is not justified due to their distinct patterns of associations with criterion variables.

Two self-report questionnaires commonly used to assess levels of the Dark Triad in the general population are the Dirty Dozen (DD; Jonason & Webster, 2010) and the Short Dark Triad (SD3; Jones & Paulhus, 2014). The two scales evaluate the key components of each of the three Dark Triad traits concisely and efficiently. Although the DD possesses very high

reliability coefficients, its high reliability may be due to item redundancy. Furthermore, the convergent validity of the DD pales in comparison to that of the SD3, particularly when the two scales are correlated with lengthier, established measures of the Dark Triad. Specifically, the DD reflects less of the variance in the established Dark Triad measures than does the SD3. Recently, researchers have proposed that the trait known as subclinical sadism, characterized by the engagement in cruelty for pleasure or subjugation, should be included with a triad to form a "Dark Tetrad" of personality. Promising subclinical sadism measures have been developed including the Assessment of Sadistic Personality (Plouffe, Saklofske, & Smith, 2017), the Short Sadistic Impulse Scale (O'Meara, Davies, & Hammond, 2011), and the Comprehensive Assessment of Sadistic Tendencies (Buckels & Paulhaus, 2014).

Psychopathy

The most recent of the three Dark Triad traits to emerge in subclinical literature is psychopathy, which is characterized by impulsive thrill-seeking, aggression, callousness, erratic behavior, low empathy, and low anxiety. High-psychopathy individuals use charm and manipulation to satisfy their needs. While psychopathy appears to be closely related to Machiavellianism, high scorers on Machiavellianism exhibit tactical interpersonal manipulation, whereas the psychopath acts impulsively and violates social norms without a plan in place.

Most previous literature has examined psychopathy as it emerges in clinical populations such as offenders, inmates, and psychiatric patients. In 1968, the Diagnostic and Statistical Manual of Mental Disorders (DSM-II) described individuals exhibiting high levels of psychopathy as unsocialized, selfish, impulsive, and unable to learn from experience. The gold standard for measuring psychopathy among clinical populations is Hare's (1991) Psychopathy Checklist – Revised (PCL-R). The PCL-R was designed to assess a psychopath's affective deficits and antisocial behavior tendencies. The PCL-R splits psychopathy into two dimensions known as primary and secondary psychopathy. Primary psychopathy reflects the psychopath's heritable affective deficits, including a lack of remorse, high manipulativeness, and high callousness. Primary psychopathy is associated with Machiavellianism and narcissism, as well as low empathy. Secondary psychopathy reflects an environmentally acquired affective disturbance, and is linked to greater instances of antisocial lifestyle choices such as criminality and substance abuse. More recently, a three-factor model of psychopathy has been proposed, such that individuals exhibiting psychopathic tendencies are described as being affectively deficient, impulsive, and deceptive in interpersonal contexts.

In recent years, researchers have contended that if psychopathy is a personality trait, then it should not only emerge among clinical populations, but also among the general population. It has been estimated that individuals exhibiting psychopathic traits make up approximately 1% of the general population and 15–20% of prison populations. In order to assess psychopathy at the subclinical level, the Self-Report Psychopathy Scale (SRP; see Hare, 1985) was developed. The SRP-III (Paulhus, Neumann, & Hare, in press), which is the most recent version of the SRP, evaluates levels of subclinical psychopathy using 64 self-report questions measured on a 5-point Likert scale, where participants rate their level

of agreement on a series of statements. The SRP-III is analogous to the PCL-R, with the main departure being the populations assessed (i.e. the SRP-III measures the general population as opposed to the clinical population). The SRP-III contains four subscales representing separate domains of psychopathy: Interpersonal Manipulation, Callous Affect, Erratic Lifestyle, and Antisocial Behavior. Several studies have indicated that the measure possesses strong reliability coefficients and validity.

Psychopathy is negatively associated with honesty-humility, agreeableness, conscientiousness. Psychopathy is also associated with self-enhancement, operationalized as the discrepancy between self-reported IQ scores and actual IQ scores. Individuals high in psychopathy further demonstrate a propensity to lie and cheat in a multitude of situations, including in academic and mating contexts. Moreover, they derive greater pleasure from lying and cheating relative to high Machiavellianism or high narcissism individuals. It is no surprise then, that psychopathy is seen as the least desirable of the Dark Triad traits, as it offers few benefits to the self or others.

Narcissism

Narcissism is characterized by a grandiose sense of self-importance, dominance, superiority, and entitlement. The tremendous arrogance and fantasies of unlimited power and success are features that set those high in narcissism apart from those high in subclinical psychopathy and narcissism. High scorers on narcissism require excessive admiration and believe that they are special, and as such, insist on associating with only high-status people. These individuals feel entitled and exploit others for personal gain. Narcissists are also envious of others, believe people are envious of them, and will diminish others' success or accomplishments. Like the other Dark Triad traits, individuals high in narcissism demonstrate a lack of empathy for others.

Narcissism first emerged in the early twentieth century and was viewed as part of normal human development. The first narcissism theorists were psychoanalysts who relied on observations of their clinical patients. These observations led to the belief that narcissism was a part of psychosexual development as well as a means of self-preservation. It was not until 1925 that narcissism was viewed as a personality trait. Individuals with this personality type were characterized as being preoccupied with themselves, feeling a sense of superiority, and demonstrating a persistent lack of empathy. By the mid-twentieth century, narcissism emerged as a personality disorder that was diagnosed by observable behavior resulting in the clinical term Narcissistic Personality Disorder (NPD).

It was not until the late 1970s that narcissism was recognized as a subclinical, and not just a clinical trait. The development of the Narcissistic Personality Inventory (NPI; Raskin & Hall, 1979) allowed for measurement of subclinical narcissism. Subclinical narcissism shares similar facets with clinical narcissism such as grandiosity, dominance, superiority, and entitlement, but lacks the vulnerable features, and is considered less extreme. The NPI is a 40-item forced-choice questionnaire that allows participants to choose between two options (e.g. A. I only associate with high-class people, or B. I don't care about a person's social status). High scores on the NPI indicate high levels of narcissism.

Subclinical narcissism is significantly correlated with three of the Big Five personality factors. Specifically, high scorers on clinical narcissism are more extraverted and open to experience, but they are less agreeable. They also suffer from a self-enhancement bias and tend to overestimate their intelligence and performance compared to others. Furthermore, subclinical high scorers on clinical narcissism tend to behave aggressively when their ego is threatened, more so than individuals with subclinical psychopathic or Machiavellian traits.

Typically, narcissists report having numerous high quality interpersonal relationships. However, when self- and partner reports are examined, narcissists appear to exaggerate the quality and quantity of these relationships. Specifically, regarding romantic relationships, narcissists appear to be desirable partners at the beginning of relationships, but eventually the grandiose self-absorption becomes problematic for the partner and leads to dissolution of the relationships.

Machiavellianism

Machiavellianism derives from the sixteenth-century writings of Niccolò Machiavelli, where he expressed the view that the most effective monarchs are self-serving and deceitful in his book *The Prince*. In the 1960s, Richard Christie conceptualized Machiavellianism as a personality trait broadly defined by the manipulative nature reflected in Machiavelli's writings. By creating a series of personality assessment items based on Machiavelli's description of the trait characteristics, Christie demonstrated that individuals vary along a continuum of Machiavellianism, providing evidence for individual differences in levels of the construct.

Machiavellianism is characterized by deception, self-interest, and manipulation. Individuals exhibiting high levels of Machiavellianism commonly use a number of manipulation tactics such as flattery for interpersonal gain or to further their own interests. Machiavellians tend to possess a cynical worldview in which they are unlikely to demonstrate concern for the welfare of others above their own well-being. Machiavellianism bears a closer resemblance to psychopathy, relative to narcissism. Both Machiavellianism and psychopathy are negatively associated with conscientiousness.

However, unlike the impulsive nature of the psychopath, those high in Machiavellianism are more likely to carefully and deliberately plan ways to exploit others in order to further their own interests, such as in short-term mating situations. In order to derogate mating competitors, those high in Machiavellianism are more likely than high-psychopathy individuals or high-narcissism individuals to speak about the competitor in an offensive or rude way, providing evidence for their lack of morality and concern for others. Furthermore, those high in Machiavellianism are less susceptible to self-enhancing biases than are high-psychopathy individuals and high-narcissism individuals. Despite these differences, both those high in Machiavellianism and high-psychopathy individuals tend to exhibit emotional detachment in interpersonal relationships. Furthermore, those high in Machiavellianism, along with high-narcissism individuals, are described as more likely to be interpersonally irritating than threatening.

High scorers on Machiavellianism are perceived to be intelligent and attractive by their peers. However, Machiavellianism is unrelated to real world success or intelligence, perhaps due to their tendency to engage in unethical and dishonest behaviors such as lying,

stealing, or cheating. It is not surprising, then, that high Machs are more likely to cheat and plagiarize in school than are low or non-Machs, especially in situations where there is a low likelihood of cheating being detected. In interpersonal relationships, Machiavellians tend to lack empathy and possess an internal locus of control. Researchers have speculated that this is due to their expectation of control and focus on the self in social interactions. In all other domains, however, Machiavellians tend to possess an external locus of control.

High scorers on Machiavellianism tend to exhibit a cognitive style that is low in complexity. Researchers have contended that this is due to the notion that non-Machs are more interpersonally sensitive to others' needs and emotions, and individuals who display these interpersonal characteristics are more likely to possess more complex interpersonal systems. Thus, those high in Machiavellianism do not display the same high interpersonal cognitive complexity as do non-Machs.

The most commonly employed assessment tool for Machiavellianism is the 20-item MACH-IV (Christie & Geis, 1970). The MACH-IV is a self-report questionnaire consisting of three subscales: Morality, Tactics, and Views. The MACH-IV is measured on a 7-point Likert scale where participants rate their agreement with a series of statements. Previous literature has indicated that the measure possesses strong reliability coefficients and validity.

Decisional Styles

Annamaria Di Fabio and Ornella Bucci

University of Florence, Italy

Definition of Decisional Styles and Indecisiveness

Decisional styles and indecisiveness are relevant constructs in relation to career decision-making process. Decisional style was defined as a habitual pattern individuals that use in decision-making (Driver, 1979); the typical way, as a personal characteristic of the decision-maker, to perceive and respond to the decision-making tasks (Harren, 1979); a habit learned that is different among individuals regarding the amount of information and the number of alternatives considered in the decision-making process (Driver, Brousseau, & Hunsaker, 1993). Scott and Bruce (1995) define decisional style as "the learned habitual response pattern exhibited by an individual when confronted with a decision situation. It is not a personality trait, but a habit-based propensity to react in a certain way in a specific decision context" (p. 820). They identify five decisional styles: rational (a thorough search for and logical evaluation of alternatives); intuitive (a reliance on instincts and feelings); dependent (a search for advice and direction from others); avoidant (attempts to avoid decision-making); spontaneous (sensations, immediate intuitions, and desire to make the choice quickly).

  Mann, Burnett, Radford, and Ford (1997) define decisional styles as the individual differences in how people face the psychological conflicts emerging in the decision-making process. They individuate the following decisional styles: the adaptive one is vigilance (a careful and adaptive approach, directed to the clarification of the objectives to be achieved through the decision-making process and the evaluation of each alternative before deciding). The maladaptive decisional styles are: avoidance (the tendency to avoid decision-making by assigning the responsibility of the decision to others); procrastination (the tendency to postpone the moment of addressing the decisional conflict); hypervigilance (the tendency to search frantically for a way to resolve the decisional conflict). In particular, the model by Scott and Bruce and the model by Mann et al. can be considered models of reference.

More recently, Thunholm (2004) gave an integrated definition of decisional style that is "the response pattern exhibited by an individual in a decision-making situation. This response pattern is determined by the decision-making situation, the decision-making task, and by the individual decision-maker. Individual differences between decision makers include differences in habits but also differences in basic cognitive abilities such as information processing, self-evaluation and self-regulation, which have a consistent impact on the response pattern across different decision-making tasks and situations" (p. 941).

In the decision-making literature, the indecisiveness construct is also relevant. It refers to the inability to make decisions in a timely manner in different situations and domains of life; a chronic inability to make decisions in diverse contexts (Frost & Shows, 1993). Indecisiveness represents an individual's problem in taking decisions in any part of his or her own life. Indecisive subjects can thus be defined as individuals with problems in taking any kind of decision, regardless of its importance.

Measurement of Decisional Styles and Indecisiveness

The two more frequently used measures of decisional styles are the General Decision-Making Style (GDMS; Scott and Bruce, 1995) and the Melbourne Decision Making Questionnaire (MDMQ; Mann et al., 1997).

The GDMS contains 25 items with response options on a 5-point Likert-type scale, ranging from 1 (*strongly disagree*) to 5 (*strongly agree*). It assesses five decisional styles: Rational (e.g. "I make decisions in a logical and systematic way"); Intuitive (e.g. "When I make decisions, I tend to rely on my intuition"); Dependent (e.g. "I rarely make important decisions without consulting other people"); Avoidant (e.g. "I avoid making important decisions until the pressure is on"); Spontaneous (e.g. "I generally make snap decisions").

The MDMQ is composed of 22 items with a response options on a 3-point Likert scale (1 = *not true*, 2 = *sometimes true*, 3 = *true*). It assesses four decisional styles: Vigilance (e.g. "I am very careful before making a choice"), Avoidance (e.g. "I avoid making decisions"); Procrastination (e.g. "I postpone making decisions until it is too late to make a choice"); Hypervigilance ("Whenever I face a difficult decision I feel pessimistic about finding a good solution").

The more frequently used measure of indecisiveness is the indecisiveness scale (IS, Frost & Shows, 1993). This scale measures indecisiveness using 15 items, with a 5-point Likert-type response scale (from 1 = *strongly disagree* to 5 = *strongly agree*). Examples of items are: "When ordering from a menu, I usually find it difficult to decide what to get"; "It seems that deciding on the most trivial thing takes me a long time."

Similarities of Decisional Styles and Indecisiveness to Other Constructs

Decisional styles and indecisiveness are studied in relation to personality traits to examine similarities and specificities.

Decisional styles are not personality traits even if they are associated with Big Five personality traits. Relations emerged between decisional styles according to the Scott and Bruce (1995) model and Big Five personality traits. Extraversion is positively associated with intuitive and spontaneous decisional styles, that are relative to modalities of decision based on instincts, feelings and sensations, immediate intuitions. Openness is positively associated with intuitive decisional style, underlining the importance of openness to experience for a decisional style based on sensations and intuitions. Agreeableness is positively associated with dependent decisional style, probably because agreeable individuals are more cordial and cooperative and so they could be more dependent on the judgment of other people. Conscientiousness is positively associated with rational decisional style, characterized by search for the logical evaluation of alternatives. Neuroticism is positively associated with avoidant decisional style, linked to attempts to avoid anxiety related to the decision-making process.

According to Mann et al. (1997) model, relations emerged with Big Five personality traits. Particularly, with respect to extraversion a positive relation emerged with vigilance and inverse relations emerged with maladaptive decisional styles of avoidance, procrastination, and hypervigilance. Extraverted individuals have the tendency to be social, enthusiastic, optimistic, energetic. These characteristics facilitate a vigilant decision-making style. Also in relation to agreeableness a positive relation emerged with vigilance and inverse relations emerged with avoidance, procrastination, and hypervigilance. Individuals with high agreeableness have the tendency to be cheerful, adaptive and co-operative. They have a high level of activity or enthusism to do any kind of tasks. They will be able to interact with many people to collect and share information to solve decisional problems. So more agreeable individuals could also be more vigilant.

Furthermore, concerning conscientiousness, a positive relation emerged with vigilance and inverse relations emerged with avoidance, procrastination, and hypervigilance. Conscientious people have to be goal-directed and motivated and these characteristics are fundamental for the vigilant decision-maker who evaluates alternatives and develops strategies to reach desired goals. With respect to openness, a positive relation emerged with vigilance and inverse relations emerged with avoidance, procrastination, and hypervigilance. Individuals with high openness tend to be receptive to new ideas and are curious. These characteristics are important for a vigilant decision-maker and for the capacity to develop adaptive strategies in decision-making. Finally, regarding neuroticism, positive relations emerged with avoidance, procrastination, and hypervigilance and an inverse relationship emerged with vigilance. Neurotic individuals tend to experience negative effects, to have poor coping when they encounter stress and have the tendency to perceive more negative life events. Making decisions can be stressful and vigilant decision makers can have confidence to handle this stress and so reach a productive decision.

Regarding similarities and specificities of indecisiveness in relation to personality traits, relations emerged between indecisiveness and different personality characteristics. Indecisiveness results from trait anxiety, obsessive compulsive phenomena, and perfectionism.

Indecisiveness is also associated with Big Five personality traits. In particular, a positive relation emerged between indecisiveness and neuroticism, underlining a general tendency to experience negative feelings of anxiety and distress associated with experiences of difficulty and discomfort in making decisions. Furthermore, an inverse relation

between indecisiveness and conscientiousness emerged, highlighting that characteristics such as self-discipline, perseverance, and a tendency to complete tasks were negatively associated with problems completing decisional tasks. An inverse relation between indecisiveness and extraversion also emerged, underlining characteristics such as being energetic and gregarious were negatively associated with the research of support from others that can be helpful in decision-making.

Explanations of Decisional Styles and Indecisiveness

The research regarding explanation of decisional styles and indecisiveness is particularly focused on psychological antecedents.

Regarding psychological antecedents of maladaptive decisional styles, it is possible to underline irrational belief (as for example, belief that there is a unique possibility of right choice, belief that once a decision is made it cannot be changed), anxiety, fragile self-esteem, lack of information. Adaptive decisional styles are favored by better capacity for problem solving and searching for information, high self-esteem and positive self-concept, high ability to manage emotions connected to decision-making process.

Concerning indecisiveness, some antecedents were individuated in a tendency to experience negative emotions in a wide range of situations including decision-making. Trait anxiety, obsessive compulsive phenomena, and perfectionism could be antecedents of indecisiveness. Also difficulties in emotion-regulation could contribute to indecisiveness.

Dealing with Decisional Styles and Indecisiveness

In the literature, some programs to enhance decisional styles exist. In particular, specific programs were developed to enhance adaptive decisional styles according to the two principal models of Scott and Bruce (1995) and Mann et al. (1997).

The training based on the Scott and Bruce model (1995) aimed to develop a rational style in decision-making that is characterized by a thorough search and logical evaluation of alternatives. The exercises are focused on the development of this rational approach to decision-making, promoting the rigorous collection of information and a detailed evaluation of different options.

Regarding the model by Mann et al. (1997), the traditional enhancement program is the GOFER. This program is based on the theory of decisional conflict by Janis and Mann (1977) that describes the decision-making process undertaken in difficult and stressful conditions. The GOFER aims to promote decision-making, increasing a vigilant decisional style. In fact the vigilance requires an accurate information elaboration to lead to a more careful decision. The GOFER is applied with a group modality and is articulated in different units focused on various aspects of decision-making as for example decisional problem solving, survey values and objectives, considering a wide range of alternative actions, searching for information, weighing the positive and negative consequences of the options, planning how to implement the options.

Furthermore, programs to deal with indecisiveness are based on exercises that permit clarification of one's own decision-making goals, consideration of the costs of not making a decision, enhancing decision-making problem solving, managing emotions, and focusing on concrete elements rather than on one's own emotions in making a choice.

Defense Mechanisms, Contemporary Perspectives

Aleksandar Dimitrijević

International Psychoanalytic University, Berlin, Germany

The concept of defense mechanisms was first introduced by Sigmund Freud in 1895, as part of his theory of the dynamic unconscious and as part of his understanding of psychopathological phenomena and their treatment. In Freud's conception, psychic life was a constant battle between wishes and prohibitions. While wishes, connected by Freud with the unconscious drives, influence human behavior and decisions, prohibitions make possible civilized life, where only certain wishes can be satisfied in a certain way. To find a compromise between the two, the Ego deploys defense mechanisms in order to find a non-prohibited satisfaction in reality or fantasy.

Defense mechanisms are unconscious (just as drives and wishes are) and are being activated automatically. It is impossible for one to decide whether to use them or not. This makes it difficult for us to recognize that we are using defense mechanisms or to introduce changes in the modes of usage.

The function of defense mechanisms can be twofold. First it is related to the reduction of anxiety provoked by forbidden wishes, as described above. Second, they may help us achieve and/or retain social desirability and make (almost) perfect self-representations, hiding unacceptable wishes from ourselves and others.

Defense mechanisms are not pathological phenomena per se. They are used by everyone in our everyday lives and are rather helpful. If they are, however, used too frequently and/or too rigidly, that may lead to specific character structures and mental disorders, while some defense mechanisms are believed to be typical for certain mental disorders (see below). One effect of psychotherapeutic treatments should be to make inner conflicts less intense and thus defense mechanisms less needed and more flexible.

Types of Defense Mechanisms

The most comprehensive account of defense mechanisms was provided in the 1936 book *The Ego and the Mechanisms of Defense* by Anna Freud. In it, the following mechanisms were described:

- repression: this is the most effective and direct defensive mechanism. Repression reduces anxiety by keeping a mental image (and not the drive wish) out of consciousness. It is the basis of most other defense mechanisms, which work in indirect ways, only if/when the repression could not do the job. It is also a rather "expensive" mechanism, because one must constantly invest energy in not letting the image return to consciousness. It is considered to be typical for hysteric personalities;
- isolation: this mechanism divides an experience or memory from emotions, so that it remains "dry" and does not provoke anxiety: "the experience is not forgotten but instead is deprived of its affect, and its associative connections are suppressed or interrupted so that it remains as though isolated" (Freud, 1926, p. 120). It is considered to be typical for obsessive personalities;
- projection: this mechanism externalizes unacceptable wishes, affects, or internal objects, so that you recognize them in other people and believe they have them and not you. It is considered to be typical for paranoid as well as phobic disorders;
- introjection: this mechanism was introduced by Sandor Ferenczi in his first psycho-analytic paper, presented in 1908. Opposite to projection, it refers to a process of making something external become a part of the Ego or Super-ego, but not fully integrated. As it is frequently connected to the loss of an important object, it is considered to be typical for depression (Freud still used the term melancholia). Introjection can also be a normal developmental process, a way to acquire skills, and gain knowledge;
- reaction formation: this mechanism is based on exaggerated expression of the emotion opposite to what we really feel, for instance being too kind to someone with whom we are angry. It is believed that it starts forming in the anal phase, under the influence of the Super-ego, and leading very quickly to generalizations;
- regression: this mechanism makes the Ego retreat to more primitive ways of functioning, satisfaction, and relationships, for instance like a child who is faced with sharing attention with a younger sibling and starts behaving like an infant;
- reversal into the opposite: this mechanism refers to turning passive experience into active action or vice versa;
- undoing: this mechanism includes an action that is aimed at erasing impulses that might cause anxiety, even if they are related to positive experiences (like therapeutic improvement); obsessive personalities.

In the work of Sigmund Freud, several defense mechanisms were described that did not make it to the above list:

- displacement: this mechanism substitutes a forbidden object with another that is acceptable or less threatening for the Ego, so that original wishes are kept out of consciousness. It can be applied to thoughts, relationships, emotions or time;

- sublimation: this mechanism is explained by Freud's idea (1908) about "the capacity of the sexual instinct to alter its original aim into a non-sexual aim that yields socially valued activities." It was most frequently applied to intellectual and artistic activities, but later also to turning aggression into motivation to become a surgeon. Because it allows satisfaction without repression, sublimation is considered to be the most sophisticated defense mechanism.

In the coming decades, the so-called more primitive defenses were described (mostly by Melanie Klein, subsequently by Otto F. Kernberg). This term implies that the defense mechanisms belonging to this group are developmentally earlier and that they are mostly used by persons with more fragile personality organizations or those in deeply regressed states of functioning. These defenses include:

- splitting: this mechanism is a reaction to deep ambivalence and leads to division of self and/or objects into all-good and all-bad parts; it is typical of trauma-related and personality disorders;
- projective identification: this mechanism is about depositing previously split off parts of the self in the other person, who is then identified with the projected part. It is also an effort at establishing omnipotent control over others, but may also be a benign form of everyday communication;
- idealization: this mechanism is based on assigning too much value to self or others (persons, organizations, ideas), so that nothing bad can be found in them and every idea of their badness must be excluded;
- denial: this is a mechanism of avoiding anxiety by not seeing the obvious or "waiting for nothing to happen." It may be a transient state in many of us, but may also have generalized and permanent forms;
- manic defenses: this group of mechanisms is aimed against depressive anxieties via omnipotence, denial, and idealization.

Almost all of these mechanisms are present in the Diagnostic and Statistical Manual of the American Psychiatric Association, forming, thus, the basis of clinical thinking for many researchers and practitioners.

Other Conceptions of Defense Mechanisms

It is now considered that Freud's conception was under strong influence by the then-current mechanistic trends in natural sciences and also very pessimistic. In the 1960s, Gerald Caplan introduced the idea of coping mechanisms, behavioral and cognitive efforts at reducing stress and anxiety. These were similar to defense mechanisms, yet more conscious and controllable. While the improvement of defense mechanisms depended on long-term psychoanalysis, coping mechanisms can be quickly be trained. This concept was very influential in the domain of preventive psychiatry (community mental health care).

George Vaillant (1992) introduced "more mature" or "highly adaptive" defenses: altruism, humor, suppression, anticipation, sublimation. These are, in his opinion, used voluntarily and not in relation to conflict. Vaillant also did a lot of empirical research in order to demonstrate the importance of these mechanisms.

Empirical Research on Defense Mechanisms

The number of empirical studies about defense mechanisms has increased over the last couple of decades. Reviewers have concluded that the concept has received "impressive confirmation" and that the best documented are the mechanisms of reaction formation, isolation, and denial (Baumeister, Dale, & Sommer, 1998). Among the most relevant studies in the domain of social and personality psychology are the following:

- about reaction formation: women with high "sex guilt" reported not being sexually aroused by erotic stimuli, while physiological measures showed otherwise; people experimentally "labelled" to be racially prejudiced would give more money to an African American than to a Caucasian beggar;
- about projection: men who were told they had homosexual tendencies started attributing more homosexual tendencies to other men; in another study it was found that projection was active, but not like psychoanalytic literature would expect it to do: the repressed thoughts were more available and then shaped the perception of social interactions;
- about displacement: in an experimental study, subjects were intentionally frustrated and blood pressure dropped most in those who expressed anger at the person who caused the frustration compared to an assistant or student. This is related to what in research literature is often called excitation transfer and scapegoating. It is important to note that this experiment fails with narcissists;
- about undoing: there is a lot of experimental evidence for this conception, also known as counterfactual thinking. It was shown that it does not change the perception of the past or remembrance;
- about isolation: those prone to repression do not have fewer unhappy memories, but process them in a minimal, rushed and superficial way, or concretely like in suicide notes, and fail to connect them into associative networks. In research literature, it is called "temporal bracketing": a past fault has nothing to do with the present self;
- about suppression: it was shown that people can be partly successful in suppressing thoughts, but that these thoughts would then return more frequently (Baumeister et al., 1998);
- about denial: it was found that people use more external attributions for failure than for success. It was noticed by health psychologists and described as "unrealistic optimism" or "the illusion of unique invulnerability." There is some evidence that it is most prominent in trauma survivors.

Depression

Katerina Rnic and David J. A. Dozois

University of Western Ontario

Depression is a common and debilitating disorder that is highly recurrent. It is associated with significant economic, social and personal cost due to the number of sick days, medical expenses, and lowered quality of life it engenders. Depression is the leading cause of disability worldwide (WHO, 2012), and accounts for $60 billion in lost productivity in North America each year. Individual suffering is considerable; depression predicts divorce, poor interpersonal and occupational functioning, and low socio-economic status. Approximately 4–7% of depressed individuals kill themselves, and depression is associated with greater risk of obesity, metabolic syndrome, diabetes, stroke, and all-cause mortality (see Gotlib & Hammen, 2014).

An episode of major depressive disorder (MDD) is defined by the Diagnostic and Statistical Manual of Mental Disorders (DSM-5; APA, 2013) as a period of at least two weeks of low mood (or irritable mood in children) and/or anhedonia (i.e. loss of interest or pleasure in previously reinforcing activities). Additional symptoms include changes in appetite or weight (increase or decrease), changes in sleep (insomnia or hypersomnia), psychomotor agitation or retardation, low energy or fatigue, poor concentration or difficulty making decisions, excessive or inappropriate guilt or feelings of worthlessness, and thoughts of death or suicide. Diagnostically, an individual must experience five out of nine symptoms. It is important to note that individuals from non-Western cultures are more likely to endorse somatic symptoms, such as disturbances in sleep, energy, or appetite, than affective symptoms, such as depressed mood. As well, diagnosticians must use their clinical judgment to determine whether depressive symptoms constitute an episode of MDD, or are a normative reaction to a major stressful life event involving loss (e.g. financial ruin, bereavement), whereby a diagnosis of MDD should be deferred.

Dysthymia, also known as Persistent Depressive Disorder in the DSM-5, is characterized by depressed mood (or irritable mood in children) experienced for at least two years (or one year in children), during which there are no more than two consecutive months that the individual is asymptomatic. In addition to low mood, individuals must also experience at least two other symptoms, some of which overlap with MDD (i.e. changes in appetite,

changes in sleep, low energy or fatigue, poor concentration or indecisiveness), and others that are unique to the criteria set for dysthymia (i.e. low self-esteem, hopelessness), despite their common occurrence in individuals with MDD.

Epidemiology

MDD is among the most common mental disorders. Lifetime prevalence rates are 14.6% in high-income countries and 11.1% in low- to middle-income countries, and 12-month incidence rates are 5.5% and 5.9% in high- and low- to middle-income nations, respectively. Average age of onset of depression is during young adulthood (early to mid-twenties; APA, 2013), although first onset in late adulthood is not uncommon, and first onset in childhood and adolescence is becoming increasingly prevalent. Adolescent and adult females are 1.5–3 times more likely to experience depression than their male counterparts. However, in prepubescent children, there appears to be no gender difference in prevalence. Episodes of major depression last approximately 6–9 months on average (APA, 2013), and the majority of individuals spontaneously remit from an episode within 3–12 months (see Gotlib & Hammen, 2014 for a review of epidemiological findings).

The chronicity of depression largely accounts for its devastating personal and societal burden, whereby 50% of individuals who experience one episode of depression will experience another, and up to 90% of individuals who have experienced two or more episodes will suffer a recurrence. Risk of recurrence increases with each episode, and periods of wellness between episodes often become shorter as the disorder progresses. On average, individuals diagnosed with MDD experience five episodes in their lifetime. However, the course of the disorder varies substantially across individuals, such that some individuals rarely or never experience remission, whereas others experience years of full remission between discrete episodes, and still others only experience a single episode.

Those individuals with comorbid psychiatric disorders are more likely to have severe and chronic depression, and are less likely to respond fully to treatment. Comorbidity is the rule rather than the exception; for example, more than 50% of individuals with depression also have an anxiety disorder. Individuals with dysthymia are at an even greater risk of psychiatric comorbidity. Dysthymia is also associated with greater functional impairment, stress, dysfunctional personality traits, family history of depression, and younger age of onset than MDD.

Causal Factors

No single factor causes depression. Rather, the disorder results from an interaction of environmental, psychological, biological, and characterological risk factors. As with other disorders, vulnerabilities typically interact with stress in the environment to trigger the onset of a disorder in what is referred to as the diathesis-stress model. Severe life events, particularly those involving loss, are often associated with the onset of a depressive episode, particularly episodes occurring earlier in the course of the disorder. This stress likely interacted with a pre-existing risk factor, or diathesis, such as a cognitive vulnerability or biological

liability. Stressors occurring early in life, particularly childhood maltreatment, may result in maladaptive core beliefs, a cognitive vulnerability that, when activated by stress later in life, may result in depression.

Cognitive models posit that depressed individuals appraise situations more negatively than non-depressed individuals do. For example, depressive thinking is characterized by a number of cognitive distortions, including jumping to conclusions without requisite evidence and engaging in all-or-nothing thinking. These distortions are driven by schemas, which are organized core beliefs about the self, world, and future. Schemas containing negative content tend to be tightly interconnected and schemas containing positive information are diffuse in depressed individuals as compared to their non-depressed counterparts. Negative schemas filter information to fit with the individual's negative beliefs, thereby affecting how he or she attends to, encodes, retrieves, and interprets information. In turn, these negative cognitions result in both negative affect and maladaptive behavior.

Maladaptive behaviors are often aversive to others in the social context, and unsurprisingly, depression is associated with poor quality interactions, social deficits, and interpersonal stress. Depressed individuals are less expressive, engage in poor eye contact, and actively seek criticism from others that is consistent with their schemas ("negative feedback seeking"). They also engage in excessive reassurance seeking, a tendency to persistently seek assurance about one's worth and lovability regardless of whether that assurance has already been provided. These behaviors can result in conflict and rejection from close others. Consistent with these findings, individuals with depression have been found to generate stress, particularly in the interpersonal domain, which further exacerbates symptoms and is an important mechanism for maintaining the disorder.

Biological models of depression focus on genetic, neurochemical, and neurophysiological abnormalities associated with the disorder. Depression is associated with disrupted functioning of the serotonin, norepinephrine, and dopamine neurotransmitters, which regulate sleep, appetite, energy, activity, and pleasure. Depressed individuals also show elevated secretion of the stress hormone cortisol, which over time can result in brain cell death, particularly in the hippocampus, the part of the brain responsible for learning. Furthermore, depression is associated with sleep architecture abnormalities (less deep sleep and early onset of rapid eye movement sleep), decreased blood flow in the left frontal regions of the cerebral cortex, and overactivity of the amygdala, a brain structure implicated in processing emotions, particularly negative emotions.

Depression also has a genetic component, with heritability rates estimated around 40%. No one gene accounts for the heritability of depression. However some genes have been implicated in gene–environment interactions. For example, individuals who experience a highly stressful life event *and* who are homozygous for the risk allele of the serotonin transporter gene are at greater risk of developing depression than heterozygotes or individuals without the risk allele. It has been hypothesized that the risk allele of the serotonin transporter gene makes individuals more sensitive to stress. Indeed, genomic transmission of temperament likely accounts for a large proportion of depression's heritability. Depressed individuals, particularly those with chronic MDD or dysthymia, tend to exhibit high negative emotionality, which reflects sensitivity and emotional reactivity to negative stimuli, as well as high neuroticism. In addition, depressed individuals experience lower positive emotionality, which is related to extraversion, sociability, and reward sensitivity. Children with

high negative emotionality and low positive emotionality may also demonstrate behavioral inhibition, which is marked by few approach behaviors, fearfulness, and social reticence. Furthermore, depression is associated with sociotropy, a personality trait characterized by excessive dependency on others and overinvestment in interpersonal relationships.

Treatment

A number of biological and psychological interventions are used to treat depression. Interventions are selected based on history of response, family history of response, symptom profile, ease of administration or access to the intervention, potential side effects, contraindicators such as other health issues, cost, and patient preference. Medications include serotonin uptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs), and tricyclic antidepressants. These all function by increasing levels of the neurotransmitters serotonin, dopamine, and norepinephrine in the brain to varying extents. However, these medications have side effects; they do not work for all patients, and if patients discontinue their use, they will likely relapse.

Psychotherapy is a useful alternative to medication as it has no side effects and prevents relapse and recurrence. Cognitive behavioral therapy (CBT) is one of the most commonly used and empirically supported therapies for depression. The goal of CBT is to help patients become more involved in reinforcing activities that give them a sense of pleasure or mastery (i.e. behavioral activation) and to help them to become aware of their thinking in order to learn to think in a more realistic manner. The therapist uses Socratic questions in order to guide the patient to make his or her own discoveries about his or her thought processes. The therapist also helps the patient to schedule reinforcing activities, to evaluate the accuracy of his or her thoughts and to come up with more balanced and accurate thoughts, and to conduct behavioral experiments to test his or her negative beliefs. Behavioral Activation has also been empirically supported as a stand-alone treatment for depression.

Other types of evidence-based therapies that are commonly used to treat depression include interpersonal psychotherapy and mindfulness based cognitive therapy (MBCT). Interpersonal psychotherapy addresses an individual's interpersonal conflicts, role transitions, grief, and social deficits with the view that depression occurs in a social context, and that disruptions in interpersonal relationships are an important type of stressor for causing and maintaining depression. Because depression is so chronic, MBCT is used to prevent relapse and recurrence in patients who have fully or partially remitted from a depressive episode with the perspective that relapse prevention is as important as symptom remission. This is achieved by teaching patients to non-judgmentally observe the present moment in order to detach from depressive, ruminative thoughts, and is efficacious for patients with three or more past episodes.

Neurostimulation and neurosurgical techniques are sometimes used for patients who are treatment-resistant (i.e. their depression has not remitted after trials of two classes of medication) and who are non-responders to psychotherapy. These include electroconvulsive therapy (ECT), transmagnetic stimulation (TMS), vagus nerve stimulation (VNS), and deep brain stimulation. All involve stimulating parts of the brain, which can result in increased blood flow, glucose metabolism, and release of neurotransmitters. Whereas ECT and TMS

are administered by applying electric and magnetic currents, respectively, through the skull, VNS and deep brain stimulation involve the surgical implantation of pulse generators. Though invasive, these interventions are promising for treating patients with chronic, severe, and treatment-resistant depression.

Future Directions

Even with state-of-the-art treatment, most depressed individuals relapse within two years. Research is needed that identifies which individuals are at risk for relapse and the causal mechanisms that underlie depressive recurrence, as well as how to best prevent recurrences. Moreover, improved matching of treatment to individuals is needed. Given the variability in response to biological and psychotherapeutic treatments, a better understanding of the neurochemical, hormonal, cognitive, and interpersonal basis of depression, and the interactions of these variables with each other and with various treatments over time, is needed.

Diagnostic and Statistical Manual of Mental Disorders, 5th Ed.: DSM-5

Catalina Sarmiento and Chloe Lau

University of Western Ontario, London, Ontario

What is the Diagnostic and Statistical Manual of Mental Disorders?

Published by the American Psychiatric Association, the Diagnostic and Statistical Manual of Mental Disorders (DSM) is an authoritative guide to the diagnosis and classification of mental disorders for clinical practice and research. The DSM standardizes diagnoses, thereby providing a common terminology to discuss psychopathology. Its influence is seen in an array of settings and systems, including public health policies, education, reimbursement systems, research, and forensic science.

Historical Overview

In 1949, the World Health Organization released the sixth edition of the International Classification of Diseases and Related Health Problems (ICD). This was the first edition to include a chapter on mental disorders. In response to the ICD-6, the American Psychiatric Association developed its own classification system, the DSM, which was first published in 1952.

The DSM-I was the earliest formal manual of mental disorders to focus on clinical use. It was influenced by the psychobiological approach of Adolf Meyer, which conceptualized mental disorders as stress reactions, and the psychoanalytic approach of Sigmund Freud, which emphasized unconscious forces. In 1968, the next edition was released. It introduced new disorders and increased compatibility with the ICD. The DSM-II was more influenced by a psychoanalytic approach than its predecessor, and no longer referred to disorders as "reactions" (e.g. schizophrenic reaction). The diagnostic definitions of the DSM-I and DSM-II were brief, vague, and did not include specific criteria.

There were several challenges that psychiatry encountered in the late 1960s and 1970s. These included the advent of other mental health professionals that had different theoretical orientations, polemics regarding asylum conditions, research that uncovered unreliability in diagnoses, and criticism of unproven etiological assumptions of the DSM. These events

contributed to a paradigm shift in psychiatry, away from a psychoanalytic approach and toward a biomedical model.

Consequently, the third edition of the DSM was radically different from its predecessors. The DSM-III placed a great deal of emphasis on empirical research, and field trials were conducted prior to its publication in 1980. It outlined specific inclusion, exclusion, and duration criteria for each disorder and did not endorse any theory of psychopathology. The DSM-III also introduced a multiaxial system such that diagnosticians had to evaluate and rate patients on five different axes or areas of functioning (e.g. Axis I contained most mental health disorders, Axis II pertained to personality disorders and intellectual disability, Axis III relevant medical conditions). The DSM-III-R, released in 1987, removed several of the exclusion criteria, thus allowing for more comorbid diagnoses. The DSM-IV was released almost a decade later in 1994. The novel features of the DSM-III and DSM-III-R were retained, and some changes were made based on extensive literature reviews and multisite field trials. The DSM-IV-TR, released in 2000, made changes to reflect new research, correct minor errors, and update the coding scheme to better match the ICD.

DSM-5

The American Psychiatric Association began an evaluation of the DSM-IV-TR in 1999. After a series of conferences, a task force was delegated to develop the DSM-5. Thirteen work groups were established to focus on each of the major diagnostic categories. The development of DSM-5 was a comprehensive process that was composed of literature reviews, reanalyzing existing datasets, and field trials to collect new data. The field trials were held in academic medical centers, community-based clinics, and practitioners' offices. Proposed criteria were also posted for public comments on a standalone website on three separate occasions. The work groups' proposal was then evaluated and reviewed by various groups. In May 2013, the DSM-5 was released.

The DSM-5 introduced several changes in the structure of the text and diagnoses of disorders. One of the principal changes was the elimination of the multiaxial system while still stressing the importance of assessing medical conditions, psychosocial factors, and functioning. Consequently, the DSM-5 has a different organization from its predecessors. It is composed of three sections and an appendix. The first section introduces the DSM, provides a description of the development process, and discusses guidelines for proper use. The second section contains the diagnostic criteria, associated features, diagnostic issues, and epidemiology for diagnoses that are approved for clinical use. This section is organized in 20 mental disorder chapters that are positioned in the manual to emphasize the posited communalities in vulnerabilities and neurological substrates. The third section describes emerging measures, models, and diagnoses that require further study. Lastly, the appendix provides a summary of changes from the DSM-IV to DSM-5, glossaries of technical terms and cultural concepts of distress, listings of diagnoses and codes, and advisors and contributors.

To incorporate a dimensional approach, the DSM-5 now requires the diagnostician to specify the severity of the disorder (i.e. mild, moderate, severe) for many diagnoses. There is also a hybrid categorical-dimensional model for personality and dimensional assessment tools to assess the presence and severity of symptoms (i.e. Cross-Cutting Symptom

measures) in Section III. To emphasize a life course-approach, the section of Disorders Usually First Diagnosed in Infancy, Childhood or Adolescence was eliminated and the corresponding disorders were reallocated to other chapters. Other notable changes included new chapters (e.g. Obsessive–Compulsive and Related Disorders, Gender Dysphoria), new disorders (e.g. disruptive mood dysregulation disorder), transition of disorders from the section for further study to those for clinical use (e.g. binge-eating disorder), combining multiple disorders into a single diagnosis (e.g. autism spectrum disorder subsumed Asperger's disorder, autistic disorder, childhood disintegrative disorder, Rett's disorder, and pervasive developmental disorder not otherwise specified), changes to diagnostic criteria for some disorders (e.g. elimination of the bereavement exclusion for major depressive disorder), and changes in terminology (e.g. intellectual disability and intellectual developmental disorder replaced mental retardation; American Psychiatric Association, 2013).

Controversies of the DSM-5

While the DSM-5 and its predecessors have achieved widespread acceptance, the classification system is characterized by several controversies.

Inability to Capture Risk Syndromes

The DSM-5 does not currently include subthreshold or prodromal syndrome diagnoses. These risk syndromes would allow for early identification of symptomatic precursors of disorders with poor prognosis, such as schizophrenia (Tsuang et al., 2013). There is a long-standing debate as to whether subthreshold inclusions of schizophrenia, also known as the prodromal phase of psychosis, could improve the socio-occupational decline through early intervention. However, researchers and clinicians should be cautious when assessing these presentations as medicalization of normal psychological experiences could enhance stigma for the diagnosed individual. Furthermore, arguments as to whether the prodrome is valid and predictive of future psychosis persist in the scientific community. The cost-benefit risk syndromes, thus, remains unknown. At present, attenuated psychosis syndrome has been identified as a condition needing further study and included in Section III of the DSM-5 (American Psychiatric Association, 2013).

Categorical Approach to Mental Illness

Research and clinical evidence have suggested that psychological attributes occur along a continuum based on frequency and severity, rather than as categorical syndromes. However, diagnostic nomenclature in the DSM-5 is based on whether a patient demonstrates a cluster of relevant symptoms within the criteria of the syndrome, without recognizing the degree to which certain symptoms exist. Thus, important information regarding the patient's holistic psychological experience is lost by quantifying a disorder as present or absent. To address this criticism, severity specifiers have been incorporated and dimensional tools proposed. However, a dimensional conceptualization of psychopathology is still lacking in this edition.

Creating Arbitrary Boundaries of Social Constructs

Diagnostic nomenclature may be influenced by social and political factors and not just the advancement in clinical sciences. For example, homosexuality was conceptualized as a form of sexual orientation disturbance in the DSM II, and ego-dystonic homosexuality in the DSM-III. Furthermore, researchers and clinicians have questioned the validity of duration criteria (i.e. arbitrary time course of symptoms) as to whether there are true etiological distinctions that exist or arbitrary boundaries.

Future Directions DSM-5

DSM-5 Cross-Cutting Symptom Measures

In response to criticisms of the categorical conceptualization of psychopathology, the DSM-5 work groups developed and proposed the incorporation of Cross-Cutting (CC) Symptom measures. The goal of this assessment is to use dimensional measures to capture co-occurring symptoms that do not fit neatly into diagnostic criteria, but may affect functioning or distress for the individual. The cross-cutting measures consist of two levels. Level 1 consists of 13 and 12 domains for adults and child/youth, respectively. Level 2 provides a comprehensive assessment of specific domains relevant to the individual assessed. The tools can be administered at baseline and at specific intervals to track treatment response and course of the relevant symptomatology in patients over time across treatment settings (Clarke & Kuhl, 2014). The measures were placed in Section III of the DSM-5.

Such a system serves as a solution for the problem of comorbidity and greater specificity with greater accuracy in conceptualization of symptomatology during each assessment. In one study, clinicians rated dimensional measures higher than the DSM-IV in five of six aspects of clinical utility, including client communication, treatment planning, professional communication, comprehensiveness of difficulties, and description of global personality (Lowe & Widiger, 2009). The enhancement of dimensional profiles as part of regular practice shows a promising future for greater clinical utility.

Future Updates

The DSM-5 task force has suggested that the fifth edition will differ from its predecessors as it will be a "living document" that undergoes continuous revisions (American Psychiatric Association, 2013). The intent of this change is evident as the numerical convention changed from Roman to Arabic numerals to provide more frequent and consistent incremental updates (e.g. DSM-5.1, DSM-5.2).

Alternative Diagnostic Systems

There are two widely used and authoritative texts for classifying mental disorders: DSM-5 and ICD-10. The ICD-10 is more commonly used by clinicians in the European Union while the DSM-5 is more commonly used by clinicians in Canada and the United States. The ICD-10 is generated and maintained by the World Health Organization for

international standardization of diagnostic classification for health conditions and compilation of international health statistics. It includes classification of mental and behavioral disorders in Chapter V.

To address some of the limitations of the ICD-10 and the DSM-5, the National Institute of Mental Health has launched the Research Domain Criteria (RDoC) project to create a diagnostic taxonomy using biomarkers of mental disorders. The system would be analogous to those in medicine, such that mental illness is conceptualized as a brain disorder that can be objectively measured using advances in molecular genetics, genomic sequencing, and clinical neuroscience. RDoC is in its early stages of development and is, for now, a research framework rather than a clinical tool (Berenbaum, 2013).

Empathy, Personality Correlates of

Vanessa M. Sinclair and Martin M. Smith

Western University

Overview

Empathy is the ability to understand and vicariously experience the emotions of others. Whether through observation or imagination, the act of empathizing entails placing oneself in another's shoes, coupled with the experience of similar affect. Due to its key role in social interactions, empathy has long been of interest to researchers and clinicians. It is central to humanistic and positive psychology, and it is embedded in descriptions of emotional intelligence such as the Trait Emotional Intelligence Questionnaire (TEIQue; see Andre, Siegling, Aloe, Baldaro, & Petrides, 2016, for a review). However, empathy is inconsistently defined. Disagreement surrounds how to disentangle empathy from overlapping constructs such as emotional contagion, compassion, and sympathy. Nonetheless, there is a growing consensus that empathy is best understood as a multidimensional construct composed of cognitive and affective components, both with distinct neural underpinnings.

While cognitive and affective empathy are undoubtedly related, they have important conceptual differences. The affective component refers to a vicarious emotional experience – feeling what the target is feeling – and one's capacity to respond with an appropriate emotional reaction. In contrast, the cognitive component refers to recognizing, understanding, and perspective-taking, and does not imply the compassionate concern of the affective component. Though these systems work independently, they operate in concert to varying extents during an empathic experience.

Development

Although individuals of all ages differ on levels of dispositional empathy – the tendency to respond empathetically – its development across the lifespan is relatively consistent. Humans appear biologically predisposed to respond with empathy; for instance, infants as young as two weeks react with concern to the crying of other infants. Additionally, while

one may not think of toddlers as empathetic, children's ability to express concern grows alongside their self-awareness – empathetic responses can manifest as early as a toddler's second year. The ability to understand others' viewpoints continues to develop over the course of childhood.

Twin studies suggest dispositional empathy is heritable to a degree, but past findings indicate the familial environment also plays a role. As has long been known, in infancy, a caring emotional style and physical contact from the mother are linked to secure attachment. Secure attachment, in turn, has been shown to predict higher empathy (Mark, IJzendoorn, & Bakermans-Kranenburg, 2002). Infants also learn a great deal from their mothers' communication; babies raised by mothers with depression show impairment in the ability to match vocal tone with facial expressions, and produce less diverse expressions themselves. As the child grows, inconsistent and abusive rearing has been shown to stunt empathy, while responsive, authoritative parenting fosters it. Additionally, parents who model prosocial behaviors, respond positively to their children's needs, and nurture their children's cognitive development help their children develop empathy. Outside the family, co-operative play with peers may contribute to the development of empathy, as it necessitates that children consider the feelings of others.

Owing to both dynamic situational factors and static individual differences, adults vary on levels of dispositional empathy. Context matters; it is well-documented that members of one's perceived in-group elicit more empathy than those of an out-group. Empathy can also be constrained if an individual feels fearful. Other variations in empathy can be explained by stable factors such as gender and cultural identity. Culture has been comparatively less explored, but there is evidence that individuals from Western cultures express empathy differently from those from Asian cultures – Westerners appear to demonstrate comparatively more empathic concern and less personal distress (Cassels, Chan, Chung, & Birch, 2010). The role of gender has been investigated in greater detail, though there is debate regarding the extent of these differences and on the developmental reason for their existence. Regardless, women score higher on self-reported empathy, demonstrate advantages in non-verbal emotional recognition abilities such as identifying facial expressions and understanding body language, and are more likely to engage in prosocial behavior. Furthermore, disorders marked by deficiencies in empathy are more prevalent in men. Neuroimaging findings on gender differences, however, are less consistent. On the one hand, some neuroimaging studies have found structural differences in the brains of men and women. On the other hand, other studies have found that men and women demonstrate comparable neural responses while viewing another in pain (Groen, Wijers, Tucha, & Althaus, 2013).

Functions

Empathy is crucial for successfully navigating relationships. From an evolutionary perspective, the survival goals of humans are met largely through successful social interactions; picking a mate, caring for kin, and maintaining bonds are all aspects of life facilitated by empathy. The necessity of empathy is perhaps most apparent when we consider disorders characterized by its absence. Among others, autism and psychopathy involve deficiencies in the capacity to empathize, resulting in behaviors that deviate from social norms.

For individuals with autism, the inability to step into another's shoes can create problems interacting with others. These individuals often experience difficulty communicating in a way appropriate to the social context and have trouble understanding non-literal messages. In contrast, psychopaths often engage in reckless, wanton behavior with little concern for others. Non-pathological deficiencies in empathy are also associated with characteristics such as alexithymia (a term which translates to "no words for emotions"), as well as with the Dark Triad personality traits of Machiavellianism, narcissism, and psychopathy.

The ability to take another's perspective enables understanding and co-operation. As it is by definition an other-centered state, empathy predicts acts of prosociality that cannot otherwise be explained by self-serving goals. In addition to promoting positive behaviors, empathy diminishes negative ones. For example, cultivating empathy inhibits aggression, while lacking empathy is linked with violence, bullying, unstable relationships, and criminal behavior. Empathy also plays an important role in the therapeutic relationship of healthcare professionals with their clients. Humanist psychologist Carl Rogers considered it a necessary characteristic for the therapist to have, in order to ensure the client felt understood and respected. The benefits are evident in all therapeutic alliances; empathetic practitioners facilitate better health outcomes, inspire more confidence in their abilities, and have clients who report greater satisfaction with their care. Additionally, empathy plays a role in social learning. Understanding the feelings of others can help individuals better understand their environment. Seeing someone fearful, for example, can be a safe but effective way to learn about potential threats.

It should be noted that empathy is not related to exclusively positive outcomes. Individuals with particularly high amounts of empathy can experience distress, and this problem has been suggested as one explanation for compassion fatigue in healthcare professionals (a phenomenon often resulting in negative consequences for both providers and patients). Experiencing excessive empathy has been suggested to contribute to depression, though findings are mixed. It is also worth noting that in certain situations – such as where manipulation is necessary to achieve a goal – a lack of empathy could be adaptive.

Measurement

Numerous measures have been devised to assess empathy, with some instruments dating back to the 1940s. Many of these are self-report questionnaires, but empathy is also assessed using behavioral measures (such as test performance and responses to stimuli) as well as neuropsychological techniques (involving magnetic resonance imaging, MRI; electroencephalography, EEG; and measures of heart rate). Some self-report measures that capture both the cognitive and affective components of empathy include the Interpersonal Reactivity Index (IRI), the Empathy Quotient (EQ), and the Questionnaire of Cognitive and Affective Empathy (QCAE).

The IRI assesses four facets of empathy: empathic concern, personal distress, perspective-taking, and fantasy (two affective and two cognitive facets, respectively; Davis, 1983). Each of the subscales contains seven questions, for a total of 28 items. When correlating the IRI with the Big Five personality inventory, empathic concern relates highly to agreeableness, perspective-taking with a combination of openness and agreeableness, while personal

distress is largely explained by neuroticism (Mooradian, Davis, & Matzler, 2011). Some researchers dispute the importance of the fantasy subscale (which assesses the tendency to identify with fictional characters), arguing that it may not truly be assessing empathy. Fantasy also does not correlate as highly with the Big Five measure of personality. For these reasons, it is sometimes omitted.

Another more recent option is the EQ, a reliable measure of empathy that is intended to be brief and easy to administer. Designed with clinical applications in mind, the EQ was validated on a psychologically healthy sample as well as a sample of adults with autism (Baron-Cohen & Wheelwright, 2004). Critics of the EQ have argued that it measures the process of experiencing empathy rather than the underlying construct. Nevertheless, it correlates moderately with the IRI and has demonstrated good test–retest reliability.

The QCAE is a recent questionnaire that builds upon earlier tests considered psychometrically flawed. It has been argued, for example, that the EQ does not give enough consideration to the multidimensionality of empathy, and that there is difficulty in understanding the relationships between the subscales (Reniers, Corcoran, Drake, Shryane, & Völlm, 2011). The 31 items of the QCAE were derived from various empathy measures, including the aforementioned EQ and the IRI. However, as it is newer, there is comparatively less support for its validity in the literature presently.

Some researchers may choose to measure empathy using behavioral measures such as Picture Viewing Paradigms, which assess self-reported empathy based on individuals' responses to emotional images. The Picture Viewing Paradigm has good internal consistency, though test–retest reliability has yet to be demonstrated. Another possibility is the Kids' Empathic Development Scale, which assesses cognitive, affective, and behavioral aspects of empathy in school-age children, incorporating tests of emotion recognition in conjunction with self-report measures (Reid et al., 2013).

There are neuroscientific options for assessing empathy as well, typically used in conjunction with self-report and behavioral tests. MRI, which uses a magnetic field to produce non-invasive images of brain tissue, is one possibility. Functional MRI (fMRI) goes beyond MRI to produce images of neural activity levels. Findings from research utilizing these techniques have shown that individual differences in empathy correlate with aspects of brain structure, and that activity in many brain regions is associated with empathetic responding. For example, perspective-taking as measured by the IRI has been shown to correlate with gray matter volume (specifically in the left anterior cingulate). Overall scores on the EQ have been shown to correlate with gray matter volume in several regions as well. Another neuroscientific option is EEG, which measures the electrical activity produced by neurons. Findings from EEG studies have highlighted the role of the prefrontal cortex in empathetic responses. Researchers can also utilize measures of heart rate or facial electromyography – which measures muscular activity in the face – to assess distress reactions to emotional stimuli.

Emotional Competence

Moïra Mikolajczak

UCLouvain, Belgium

Although we all experience and witness all sorts of emotional episodes throughout our lives, we markedly differ in the extent to which we process, identify, understand, express, regulate and use our own emotions and those of others. The concept of emotional competence aims to account for these differences. As we will see below, the level of emotional competence is a significant determinant of the four most important aspects of people's lives: mental health and well-being, physical health, interpersonal relationships, and work performance.

Historical Background

The concept of emotional competence sporadically appears in the literature in the 1970s, becoming more commonly used after Mary Ainsworth (1913–1999; attachment theorist) suggested in the late 1970s that children's attachment style would influence their social-emotional competence. In the 1980s, developmental psychologists such as Susann Denham extensively studied children's social-emotional competence, without, however, any specific theory or measure being developed. The first theoretical model of EC, put forward by Carolyn Saarni, dates from the 1990s. According to Saarni's model, EC includes eight dimensions: (1) Awareness of one's emotional state; (2) Ability to discern others' emotions; (3) Ability to use the vocabulary of emotions and to acquire cultural scripts that link emotions with social roles; (4) Capacity for empathy with others' emotional experiences; (5) Ability to realize that inner emotional states do not necessarily correspond to outer expressions, both in one's own case and that of others; the ability to understand that one's emotional expressive behavior may impact others and the ability to take this into account; (6) Capacity for adaptive coping with aversive or distressing emotions; (7) Awareness that the structure or nature of relationships is partly defined by the way emotions are communicated in the relationship; (8) Capacity for emotional self-efficacy: the individual views herself or himself as feeling, overall, the way he or she wants to feel: one accepts one's emotional experience where this acceptance is in alignment with the individual's beliefs about what constitutes desirable emotional "balance" (see Saarni, 1999a, p. 5).

Although Saarni transforms the term "social-emotional competence" into "emotional competence," interpersonal aspects remain central to her view; this is reflected in her very definition of the concept: "Emotional competence is the demonstration of self-efficacy in emotion-eliciting social transactions" (Saarni, 1999a, p. 1). Saarni not only believes that the vast majority of our emotions are anchored in social interactions. As a socio-constructivist, Saarni also views context as a central determinant of the individual's emotional functioning: context shapes the individual's motivations to deal with an emotion-eliciting episode, the demands and affordances available to that individual, and the values and beliefs the person brings to the emotional experience. In Saarni's view, it is therefore impossible and meaningless to develop standardized instruments of measure for emotional competence, for this would disregard the contextual influences on emotional responses (Saarni, 1999c).

The fact that no proper instrument for measuring EC was developed until the 2000s probably explains why the concept of EC remained confined for so long to the field of child developmental psychology. It was finally the exponential development of the closely related concept of *emotional intelligence* which brought the concept of EC back into the spotlight, stimulated the development of EC measures for adults and fostered the diffusion of the concept in the fields of individual differences and organizational, educational, social and health psychology.

Models and Measures of Emotional Competence

The first model of emotional competence was developed by Saarni in 1999 (see above). For the reasons already explained, this model was not accompanied by a corresponding measure. Despite its potential, it could therefore never be properly validated. After the notion of emotional intelligence became popular, consultants and companies developed several models of emotional competence for assessment and training purposes. To the best of our knowledge, none of these has been scientifically validated.

In 2009, Mikolajczak proposed a model of emotional competence inspired by both Saarni's model of emotional competence (1999b) and Mayer and Salovey's model of emotional intelligence (1997). It includes five dimensions central to both models: identification, understanding, expression, regulation, and use of emotions. As shown in Table 1, this model clearly distinguishes between processing one's own emotions and processing others' emotions, in other words, between the intrapersonal and the interpersonal components of emotional competence.

A few years later, the Profile of Emotional Competence (PEC) was developed in order to test the model. The model and the measure were validated in both Western and Eastern contexts (see Brasseur, Grégoire, Bourdu, & Mikolajczak, 2013 and Nozaki & Koyasu, 2015, respectively).

Emotional Competence: Ability or Trait?

Three levels of emotional competence must be distinguished: knowledge, abilities and traits. The knowledge level refers to what people know about emotionally competent behaviors (e.g. *Do I know* which emotional expressions are constructive in a given social situation?). The ability level refers to being able to apply this knowledge in a real-world situation (e.g. *Am I able to* express my emotions constructively in a given social situation?). The focus here is not on what people know but on what they can do: even though many people know

Table 1 *A Model of Emotional Competence* (adapted from Mikolajczak, 2009).

Dimensions	Self	Other
Identification	Capacity to identify my emotions and to distinguish between discrete emotional states	Capacity to identify others' emotions
Understanding	Capacity to understand my emotions and, especially, to distinguish between the trigger and the cause	Capacity to understand others' emotions and to understand that the person in whose presence the emotion is expressed may not be the cause of the emotion
Expression	Capacity to express one's emotions and to do so adequately (at the right time, with the right person and in the appropriate manner)	Capacity to listen to others' emotions without avoidance or judgment
Regulation	Capacity to regulate my emotions when their nature, intensity, or duration is not appropriate to my goals or to the context	Capacity to regulate others' emotions when needed
Use	Capacity to use emotions when they allow better personal or professional decisions to be made	Capacity to use others' emotions in order to achieve a goal
	Intrapersonal EC	**Interpersonal EC**
	Global EC	

that they should not shout when angry, many are simply unable to contain themselves. The trait level refers to typical emotional competence, namely, the way one usually behaves in emotional situations. (*Do I typically* express my emotions in a constructive manner in social situations?) The focus here is not on what people know or on what they are able to do, but on what they typically do over extensive periods of time. For instance, some individuals might be able to express their emotions constructively if explicitly asked to do so (so they do possess the ability), but they do not manage to manifest this ability reliably and spontaneously over time. These three levels of EC are only loosely connected – declarative knowledge does not always translate into ability, which, in turn, does not always translate into usual behavior – so they should therefore be assessed using different instruments.

Knowledge and abilities are essentially assessed using intelligence-like tests such as the Situational Test of Emotional Understanding (STEU; MacCann & Roberts, 2008), the Situational Test of Emotional Management (STEM; MacCann & Roberts, 2008) or the Geneva Emotion Recognition Test (GERT; Schleger, Grandjean & Scherer, 2014). Trait emotional competence is assessed using personality-like questionnaires such as the PEC (Profile of Emotional Competence; Brasseur et al., 2013).

Importance of Emotional Competence

The literature indicates that EC, and especially the trait level of emotional competence, has a significant impact on four of the most important domains of life: well-being, health, relationships and work performance.

People with greater EC, especially (but not only) high intrapersonal EC, have enhanced well-being and fewer psychological difficulties: they are more satisfied with their lives and are less prone to depression, anxiety, or burnout. They also have better physical health, as evidenced in a recent nationally representative study conducted in collaboration with the largest mutual benefit society in Belgium (Mikolajczak et al., 2015): people with higher EC consume less medication, need less frequently to see the doctor, and are less often hospitalized.

Socially speaking, people with higher EC have more satisfying social and marital relationships; both intra- and interpersonal EC seem to contribute to this effect. Finally, people with higher EC achieve superior job performance, especially in managerial positions, stressful jobs, or jobs involving high emotional labor.

As indicated by intervention studies, EC is causally involved in these outcomes. Compared with a control group on a waiting list or receiving training unrelated to EC, people receiving EC training see an improvement in their well-being, mental and psychological health and in the quality of their social relationships (see Mikolajczak & Pena, 2015 for a summary).

Evolution and Improvement of Emotional Competence

Both intra- and interpersonal competencies develop progressively in stages from birth to approximately 8 years old. Under the joint influence of brain maturation, parents' behaviors and cultural rules, children progressively learn how to decode, express, understand, regulate and use their emotions and those of the people around them (for complete accounts, see Eisenberger & Fabes, 1992; Holodynski & Friedlmeier, 2006; Saarni, 1999b). Most competencies are acquired by the age of 8 but continue to evolve, especially in the case of emotion regulation, until the prefrontal cortex terminates its maturation around the age of 20. So, although individual differences in emotional competence are already manifested in toddlers, these differences only stabilize at the onset of adulthood. It is important to understand that this stabilization does not mean crystallization. First, except for emotion utilization, all EC improves slightly but naturally with age until approximately the age of 70 (e.g. Brasseur et al., 2013; Fantini-Hauwel et Mikolajczak, 2014). Second, like most personality traits, EC is somewhat malleable (Roberts & Mroczek, 2008). While the life experiences that are likely to change EC have not yet been studied, it has nonetheless been demonstrated that EC can improve in response to specific EC training (see Kotsou et al., 2011 and Nelis et al., 2011).

Entrepreneurship/Intrapreneurship, Personality Correlates of

Bostjan Antoncic

University of Ljubljana

Conceptualization

Entrepreneurship is considered an individual or organizational level behavioral phenomenon. The entrepreneurship-specific domain incorporates the creation and management of new businesses, small businesses, and family businesses, as well as the characteristics and special problems of entrepreneurs. Entrepreneurs are people who start up new businesses and are important for new wealth creation and economic development. Emergence-related behavioral intentions and behaviors, such as organization formation and innovation, differentiate entrepreneurship from non-entrepreneurship, which refers more to the management of existing or customary activities. Intrapreneurship is entrepreneurship in existing organizations or defined as emergent behavioral intentions and behaviors that are related to departures from the customary ways of doing business in existing organizations. Intrapreneurial processes go on inside an existing firm, regardless of its size. Intrapreneurship refers not only to the creation of new business ventures, but to other innovative activities and orientations such as the development of new products, services, technologies, administrative techniques, strategies, and competitive postures. Its characteristic dimensions are new business venturing, product/service innovation, process innovation, self-renewal, risk-taking, proactiveness, and competitive aggressiveness.

Entrepreneurs are central to entrepreneurship. The entrepreneur as a person and their role in entrepreneurship has been studied from the viewpoint of the psychological nature of entrepreneurship from the 1960s on. The psychological view is based on research on personality characteristics which largely determine who will become an entrepreneur and who will not. The psychological or personality view of the entrepreneur as a person is based on the belief that entrepreneurs differ from non-entrepreneurs (other members of the population) by personality characteristics.

Personality Correlates of Entrepreneurship

The key personality correlates of entrepreneurship can be summarized in six groups of personality characteristics: (1) need for achievement; (2) internal locus of control; (3) need for independence; (4) risk-taking propensity; (5) entrepreneurial self-efficacy; (6) the Big Five personality factors.

The theory of the need for achievement (n Ach) describes the entrepreneur as a person who compared with other groups in the population has a greater need for achievement. In the background of these needs lies the entrepreneur's desire for recognition and enforcement. The strong need for achievement motivates individuals to begin with entrepreneurship. A person with a high need for achievement tends to look for new challenges and strives to achieve recognition of their company's success or achievements. The need for achievement can be regarded as a quality of successful people, not just entrepreneurs. The need for achievement can be found in successful people from different groups, such as entrepreneurs, managers, athletes, politicians, artists, scientists, etc. The need for achievement is therefore a characteristic of successful people, including entrepreneurs.

Internal locus of control is a psychological interpretation of the entrepreneur as an individual with a sense of control over their own actualization and life. People with an internal locus of control believe that the result of their actions or work depends solely on the ability and efforts they invest and to a minimum degree on luck or coincidence.

The need for independence is a personality characteristic considered one of the strongest internal driving forces of the entrepreneur. Entrepreneurs with this characteristic are people who find it difficult to adapt to the established system and have difficulty accepting authority over them; they want to play by their own rules and decide on an entrepreneurial path or start their own business. They have a desire to assume full responsibility for their own actions.

Risk-taking propensity is a feature that is very often attributed to entrepreneurs and entrepreneurship in general. Since the early definition in the eighteenth century, the entrepreneur has been regarded as someone who assumes the risk of their business activity. For a long time it was believed that a positive attitude to risk or risky decisions and activities (a risk-taking orientation) characterizes the entrepreneurial process as well as the key figures in this process – entrepreneurs. Nevertheless, research found that entrepreneurs are willing to accept moderate risk. Entrepreneurs often thoroughly examine the possible alternatives and go into business with moderate risk. Risk-taking propensity is also not a very stable characteristic, but may vary depending on the situation. For this reason, we cannot be very confident in claiming that risk-taking propensity is a distinguishing personal characteristic of entrepreneurs. We can say that risk taking is a characteristic of the entrepreneurial process but usually not of the entrepreneur as a person.

Entrepreneurial self-efficacy can be defined as a personal conviction about one's own possibilities of successfully implementing various business functions (management, marketing, finance, etc.). Entrepreneurial self-efficacy is the personal belief in one's own ability to effectively carry out different tasks and roles; these tasks and roles are from assorted functional areas of business: marketing, innovation, management, risk taking,

and financial control. Entrepreneurial self-efficacy may be considered a personality characteristic differentiating entrepreneurs and non-entrepreneurs and a feature distinguishing successful and less successful individuals.

The Big Five factors (OCEAN) are the crucial factors that describe the general personality of an individual as follows: (1) Openness, originality, open-mindedness; defined by traits that refer to, for example, artistic, insightful, intelligent, commonplace (reversed), narrow interests (reversed), shallow (reversed). (2) Conscientiousness, control, constraint; defined by traits that refer to, for instance, deliberate, efficient, precise, careless (reversed), frivolous (reversed), irresponsible (reversed). (3) Extraversion, energy, enthusiasm; defined by traits that refer to, for example, adventurous, assertive, dominant, sociable, quiet (reversed), reserved (reversed), retiring (reversed), shy (reversed). (4) Agreeableness, altruism, affection; defined by traits that refer to, for instance, co-operative, generous, sympathetic, cruel (reversed), quarrelsome (reversed), unfriendly (reversed). (5) Neuroticism, negative affectivity, nervousness; defined by traits that refer to, for example, anxious, self-pitying, temperamental, calm (reversed), contented (reversed), stable (reversed).

The Big Five personality factors may be important for the manifestation of entrepreneurship in terms of firm start-up activities and/or intentions. The Big Five personality traits can potentially be used for predicting entrepreneurial start-ups (openness) and entrepreneurial intentions (extraversion and agreeableness). The openness personality factor may be the most important of the five factors for differentiating real-life entrepreneurs from other people. People who score higher than other people in personality traits of openness (creative, imaginative, philosophical, intellectual, complex and deep) may have a greater probability of becoming entrepreneurs than other people. Two personality factors – extraversion and to some extent agreeableness – may also be important for entrepreneurship. People who have no intention of starting up their own firms – non-entrepreneurs – tend to score lower in extraversion (traits: e.g. talkative, bold, and energetic) and somewhat higher in agreeableness (traits: e.g. sympathetic, warm, kind, and co-operative) than other people.

Personality Correlates of Intrapreneurship and Venture Success

The personality correlates of entrepreneurship described above can also be relevant for intrapreneurship. However, there may be some differences between entrepreneurs and intrapreneurs since intrapreneurs act inside an existing organization, so they need to co-operative with managers and other collaborators in the organization and may have a less expressed need for independence than entrepreneurs. The relationship between entrepreneurs' personality and success includes two sets of personality traits: broad personality traits (the Big Five) and specific personality traits (need for achievement, risk-taking propensity, innovativeness, autonomy, locus of control, self-efficacy); broad (general) traits tend to be related to success with $r = 0.15$, while specific traits tend to be related to entrepreneurial success with $r = 0.23$. Intrapreneurship can be important for the performance of companies.

Future Directions in Research, Theory, and Methodology

Personality correlates of entrepreneurs need to be researched in cross-cultural comparative studies and in studies that include sociological elements, which may be related to the formation of the personality or behavior of individuals with entrepreneurial intentions and entrepreneurs and intrapreneurs. The personality differences between entrepreneurs and intrapreneurs also need to be investigated in greater detail in future research. Theoretical models need to be, on one hand, more comprehensive (with many different correlates) and, on the other hand, more detailed (with many sub-dimensions and facets in quantitative research, as well as with more in-depth explanations of phenomena in qualitative research).

Evolutionary Theory and Personality Correlates of Mate Selection

Bernardo J. Carducci

Indiana University Southeast

Evolutionary Theory and Personality Correlates of Mate Selection

The evolutionary perspective incorporates principles of evolutionary theory to account for expression of certain personality characteristics (Buss, 2008, 2015). According to the evolutionary perspective, certain personality characteristics appear as inherited tendencies because they seem to be an adaptive response to the two fundamental challenges of evolution – survival and reproductive success. In terms of survival, the personality characteristics associated with living longer include *conscientiousness*, as such individuals are more likely to engage in health-promoting behaviors and avoid risks, and *optimism*, as such individuals are more likely to have fewer symptoms and quicker recovery when dealing with medical concerns (Friedman & Martin, 2001; Tucker & Friedman, 1996). Negatively associated with longevity are the personality characteristics of the Hostile Type A personality, as such individuals are more likely to suppress their feeling of emotional distress (e.g. anger and distress) thereby creating a greater tendency to abuse tobacco, alcohol, and drugs (Friedman, Harley, & Tucker, 1994), and *neuroticism* (e.g. moody, unstable, and overly anxious). In terms of reproductive success, the evolutionary perspective emphasizes those personality characteristics associated with functional fertile individuals (FFI) – those for whom reproduction is possible but have low rates of reproductive success. Personality characteristics for females classified as high FFI include: harm avoidance (Fasino et al., 2002), resulting in less frequent sexual intercourse; low co-operativeness, creating difficulties with potential sexual partners; and higher scores on measures of depression and anxiety, resulting in negative emotions being associated with sexual activity. In comparison to males classified as high FFI, personality characteristics for males classified as low FFI (i.e. have a greater likelihood of reproduction) include self-confidence, extraversion, and social assertiveness (Hellhammer et al., 1985), suggesting such males create more opportunities for sexual intercourse by being better able to approach potential sexual partners (e.g. being more self-confident, outgoing, and bold).

Basic Processes

A strategic expression linked to survival and reproduction is that of sexual selection (Darwin 1859/1958). Sexual selection is the process by which an organism's characteristic features evolve to promote the possibility of successful mating. A basic assumption of this process is: "Traits that increase the probability of successful reproduction will tend to increase in frequency over time" (Kenrick, Sadalla, Groth, & Trost, 1990, p. 97). Sexual selection can be divided into two forms: epigamic selection (i.e. mate selection) and intrasexual competition (cf. Figueredo et al., 2005). Epigamic selection involves the expression and evolution of characteristics that favor their selection as mates, which increases the likelihood of mating opportunities and of passing their genes on to the next generation. For example, females of a particular species might prefer to mate with socially dominant males who display the most physical strength, while males may prefer to mate with females with soft, smooth, and clean skin and other physical features associated with good health. Intrasexual competition refers to interpersonal exchanges (e.g. forms of competition) between same-sex members of the species in which superior characteristics are demonstrated to prove that one member or another is a preferable mate and to increase its potential mating opportunities (Nettle, 2009). For example, males demonstrating the most strength and greatest ability to protect the females in their territory from other males will have more mating opportunities.

Thus, not only do epigamic selection and intrasexual competition work together, but natural selection and sexual selection also work together to increase the probability of survival and reproductive success.

Consensual Preferences in Personality Characteristics

Consensual preferences in personality characteristics are preferences shared by men and women. Overall, both men and women across a variety of countries reported the characteristics they wanted most in a partner included someone who is *kind* and *understanding* and *intelligent* (Buss, 1985, 1989).

In other research, Buss and Barnes (1986) found that *exciting personality* was also included with the traits of kind/understanding and intelligent. In creating a "top-ten list" of personality characteristics, they also noted that those 10 characteristics men and women most preferred in a partner included: *good companion*, *considerate*, *honest*, *affectionate*, *dependable*, *intelligent*, *kind*, *understanding*, *interesting to talk to*, and *loyal*.

It is apparent how having a mate with these characteristics would contribute to the likelihood of a successful relationship. In taking care of each other and in nurturing their offspring, the individuals in that relationship would promote reproductive success, passing along to the next generation those genes and personality characteristics that will maximize the survival of the species. In addition, although males and females both expressed a preference for a mate with both masculine (e.g. being active and instrumental) and feminine (e.g. nurturing and expressive) characteristics, the feminine characteristics were more important than the masculine ones (Green & Kenrick, 1994). Again, it is apparent how such feminine characteristics would be important to promoting a successful relationship

with a mate (e.g. expressing one's feelings) and the care of offspring (e.g. nurturing) in a manner consistent with the processes of sexual selection. Further investigation of personality correlates of mate preference examined the preferred personality characteristics individuals had for their ideal romantic partner for the personality characteristics of Openness to Experience, Conscientiousness, Extraversion, Agreeableness, and Neuroticism included in the Big Five personality dimensions, along with the rating of their own personality characteristics for those same five dimensions (Figueredo, Sefcek, and Jones, 2006). The romantic ideal and self-ratings correlated .81 for Openness to Experience, .36 for Conscientiousness, .60 for Extraversion, .73 for Agreeableness, and .38 for Neuroticism. These results suggest that individuals prefer a romantic partner with personality characteristics similar to their own. In addition, when calculating a difference score between the romantic-ideal ratings and self-ratings, these scores indicated that individuals preferred that their romantic-ideal mate score significantly higher than themselves on Conscientiousness, Extraversion, and Agreeableness and lower than themselves on Neuroticism, with no difference being found for the Open to Experience dimension. Such a pattern of results suggest men and women both tend to want an ideal mate who is better than themselves on the positive characteristics – but not too much better, as evidenced by the correlations of similarity – and lower and somewhat different on the negative characteristics. It would seem apparent how having such an ideal romantic partner would make for an ideal relationship.

Gender-Specific Preferences in Personality Characteristics

Although males and females have consensual preferences in personality characteristics, certain gender-specific preferences exist as well (Buss & Barnes, 1986). More specifically, research investigating the preferred personal characteristics in potential mates reported that females ranked *considerate*, *honest*, *dependable*, *understanding*, *fond of children*, *well-liked by others*, *good earning capacity*, *ambitious and career orientated*, *good family background*, and *tall* higher than males. In contrast, males ranked *physically attractive*, *good looking*, *good cook*, and *frugal* higher than females. Such a pattern of results is consistent with earlier statements about mate preferences being related to survival and reproduction. For males, physically attractive mates are associated with health, reproductive success, and culinary ability; and frugality is associated with the ability to provide the domestic skills necessary to care for the family in a manner that places the fewest demands on the male – being a frugal cook eases demands on the male to provide food and other domestic resources. For females, ambitious and successful mates are associated with the ability to provide family necessities (e.g. food and shelter), while being kind, dependable, and fond of children are associated with the ability to provide care and protection for offspring and extended family. In support of such reasoning, additional research notes that the personality traits of dominance and agreeableness are related to females' perception that males scoring high on these two characteristic are more attractive (Jensen-Campbell, Graziano, & West, 1995: Sadalla, Kenrick, & Vershure, 1987) and wealthier (Jensen-Campbell et al., 1995). Such a pattern of results a consistent with the notion that dominant-agreeable males are able to provide the necessary material resources for the family while also being easy to get along with as mates and members of the greater community.

Eysenck Giant Three

Gillian C. Tohver

University of Western Ontario

Eysenck's Model

One of several major competing models in the prolific area of personality taxonomy, Eysenck's psychobiological Giant Three (also known as the Big Three, or PEN) model specifies three cumulatively non-exhaustive higher-order personality dimensions, extraversion, neuroticism, and psychoticism, located at the third level of the hierarchical personality taxonomy (Hinshaw, Kotov, Gamez, Schmidt, & Watson, 2010). While the Giant Three do show considerable overlap with other personality models such as the Giant Five, Eysenck's model is unique in its explicit specification of the traits being psychobiological (i.e. the Giant Three are defined as being caused by underlying biological bases and mechanisms such as neurological behavioral activation systems), but was not intended to be cumulatively exhaustive (i.e. many other major personality factors are not included in the Giant Three). Originally, Eysenck's dimensions were conceptualized as independent of each other, but present research now shows that the traits conceptually overlap (Latzman, Vaidya, Malikina, Berg, & Lilienfeld, 2014). Specifically, meta-analytic findings indicate that neuroticism is moderately negatively correlated with extraversion and is positively correlated with psychoticism (Hinshaw et al., 2010).

This framework, the foundation of many subsequent, converging three-factor models, has been replicated cross-culturally across the world and shows considerable longitudinal stability (Hinshaw et al., 2010). Furthermore, the Giant Three demonstrate significant utility for predicting important behavioral and life outcomes across the lifespan, from adults (for whom it was originally developed) to children and youth. Specifically, meta-analyses indicate that this model's traits contribute substantially to academic performance, occupational attainment, divorce, life satisfaction, subjective well-being, physical illness, and longevity (Hinshaw et al., 2010).

Extraversion

Eysenck's extraversion (a.k.a. positive emotionality or emotional stability) is the behavioral tendency toward positive affect and to be energized by (i.e. draw pleasure from) external and interpersonal activity (compared to being energized by internal exploration). It is a robust, primary personality factor in the Giant Three (as well as most other major personality models) that is observed cross-culturally and is described in terms of sociability, liveliness, sensation-seeking, assertiveness, activeness, dominance/competitiveness, carefreeness, surgency, and venturesomeness (Jalili & Mall-Amiri, 2015; Saklofske, Eysenck, Eysenck, Stelmack, & Revelle, 2012). Conversely, Eysenck's extraversion is indicative of poorer listening, planning, long-term concentration, and individual autonomy (Thompson, 2012; Silverman, 2012). This is essentially equivalent to the Big Five conceptualization of extraversion, though Eysenck's extraversion is also moderately positively correlated with the Big Five's openness to experience trait (Hinshaw et al., 2010; Vaidya et al., 2010).

In terms of demographic differences, Giant Three traits show variation in their practical measurement as well as their conceptual content across cultures and between genders (Bowden, Saklofske, van de Vijver, Sudarshan, & Eysenck, 2016). For example, Greek researchers have observed that male postsecondary students generally display higher levels of extraversion compared to their female counterparts, though this effect's magnitude is small (Kokkinos, Panayiotou, Charalambous, Antoniadou, & Davazoglou, 2010). Technology researchers have shown that Giant Three extraversion in young adults and youth is generally associated with greater online social media use and online sensation-seeking behaviors such as sexual content use and online competitive gaming, and with reduced non-social media internet use. Educationally, researchers have also recently found evidence that more extraverted teachers can be more effective at class management. Conversely, Giant Three extraversion is also a strong predictor of general adult delinquency (Dunlop, Morrison, Koenig, & Silcox, 2012).

Psychopathologically, researchers have found that Eysenck's extraversion is uniformly negatively related to psychological disorders, with the extraversion–disorder associations being small, and sometimes even zero in magnitude. Extraversion is highly negatively related to dysthymic disorder, obsessive–compulsive disorder, and social phobia but is independent from other phobias (Hinshaw et al., 2010). As well, extraversion shows some negative relations to the desire for perfection, depression, and social anxiety beyond that accounted for by neuroticism (Silverman, 2012). Surprisingly, though Eysenck's extraversion is generally shown to be a positive correlate of psychopathological adjustment, some recent findings indicate that the high sociability and sensation-seeking tendencies of Eysenckian extraversion are also strongly indicative of depressant use (e.g. alcohol, drugs) and adult delinquency, respectively (Feldman, Boyer, Kumar, & Prout, 2011; Dunlop et al., 2012). Likewise, meta-analytic findings suggest that average levels of Giant Three extraversion are related to antisocial personality behaviors (Hinshaw et al., 2010).

Neuroticism

Eysenckian neuroticism, or negative emotionality, is characterized as feeling, anxious, tense, guilt, depressed, low self-esteem, irrational, shy, emotional, and moody. As well, like extraversion, Eysenck's neuroticism is also the same as the Big Five model's conceptualization

of neuroticism (Hinshaw et al., 2010). Typically, Eysenckian neuroticism is higher in women and is positively associated with overall mental illness/psychopathology and behavioral maladjustment, including both internalizing and externalizing disorder symptoms and anxiety (Hinshaw et al., 2010; Kokkinos et al., 2010). However, unlike extraversion, neuroticism's relation to substance use is mixed, with some researchers observing positive relations and others no relation (Feldman et al., 2011). Interestingly, despite its tendency toward anxiety, neuroticism coincides with increased social media internet use, specifically in women; researchers have suggested this may be a method for neurotic individuals to counter their elevated feelings of loneliness.

Psychoticism

The Giant Three's most unique factor, psychoticism – more accurately known as touch-mindedness or disinhibition (vs. constraint) – reflects individual differences in under-controlled, spontaneous behavior and is characterized by descriptors such as aggressive, egocentric, cold, impersonal, unempathic, careless, unconcerned, creative, impulsive, disorganized, vindictive, cruel, and antisocial. Functionally, psychoticism is a psychopathological continuum, ranging from normal through criminal and psychopathic maladjustment, though it does not appear to predict psychosis as was previously thought. Researchers suggest that impulsivity, sensation-seeking, and lack of socialization and perseverance lie at the heart of this trait (Latzman & Vaidya, 2013). Being negatively related to trait honesty and humility, psychoticism is also strongly predictive of adult delinquency, and displays moderate to strong correlations with externalizing disorders, substance abuse, low self-esteem and decision-making ability, antisocial personality, obsessive–compulsive disorder, and other psychiatric disorders (Dunlop et al., 2012; Hinshaw et al., 2010; Vaidya et al., 2010).

Socio-developmentally, work on psychoticism has revealed that young adolescent males appear to have higher levels of psychoticism relative to their female counterparts and psychoticism levels shift with age in as little as five years (Vaidya et al., 2010). Additionally, psychoticism is associated with reduced academic achievement, internet use, and intrinsic and extrinsic religiosity. Stress researchers also note that individuals high in psychoticism respond less to stress, with psychoticism negatively correlating with stress hormone (i.e. cortisol) activity after presentation with acute stressors; however, psychoticism is independent of an individual's average (baseline) cortisol level before such acute stress.

Unlike the ubiquitous scientific support garnered for extraversion and neuroticism, the construct of psychoticism remains a controversial construct. Specifically, contemporary researchers caution that psychoticism appears to be multidimensional, significantly conceptually overlapping (i.e. being highly negatively correlated) with the Big Five's diverse agreeableness, conscientiousness, and openness traits (in fact, 33% of variance in psychoticism is explainable by agreeableness and conscientiousness; Vaidya et al., 2010), as well as with facets of the HEXACO personality model's emotionality factor (a variation of neuroticism; Dunlop et al., 2012). In fact, psychoticism's underlying components display unique relations to the abovementioned psychopathologic disorders (Hinshaw et al., 2010; Latzman et al., 2014). More pragmatically, psychoticism measurement is flawed as the psychoticism subscales of most Giant Three self-report instruments show low reliability and

cross-cultural replicability. Therefore, conceptualizing psychoticism by its underlying facets is more advisable and meaningful for understanding the construct's underlying relations to mental health and behavior.

Giant Three Measurement

A variety of self-report instruments have been developed by researchers to measure Eysenck's traits around the world. Eysenck and colleagues' Giant Three framework measures, which include the Eysenck Personality Questionnaire (EPQ; Eysenck & Eysenck, 1964), its subsequent short-form versions (the EPQ-SF, Revised EPQ-SF, and the Reduced EPQ-RS), and the Maudsley Personality Inventory (MPI), consist of self-report questions for extraversion and neuroticism (EPQ measures and MPI), psychoticism (EPQ measures only), and a set of items to test for lying/dishonesty (EPQ and MPI measures). The most recent (1994) version of the EPQ, the EPQ-R Adult, which includes both short and long test versions, has also majorly revised the Psychoticism, Extraversion, and Neuroticism scale items to follow United States norms. Eysenck's measures (full and short versions) have been adapted to both other languages (e.g. Japanese, Italian, Spanish) and to children and youth (e.g. the junior-oriented JEPQ, JEPQ-R, and JEPQ-R Short tests).

Within Eysenck's framework, lying is conceptualized as being similar to social desirability (i.e. the tendency of individuals to respond to questions in ways they believe will make them appear more desirable to others and society in general; Kokkinos et al., 2010) and honesty. In fact, Eysenck's Lying subscale is highly positively correlated with the Honesty component of another major personality theory called HEXACO, and with risk of adult delinquency (Dunlop et al., 2012). Despite the importance of participant honesty in personality research that employs self-reporting methods, researchers have questioned the validity of Eysenck's Lying subscale, as it typically shows poor reliability overall and often fails to show sufficient validity or even basic replication across different cultures (Kokkinos et al., 2010). Comparatively, the Eysenckian measures' extraversion and neuroticism scales generally show strong cross-cultural replication and validity. Importantly, scores on measures of Eysenck's Giant Three are mostly independent of respondents' general intelligence.

Extraversion, Personality Correlates of

Gillian C. Tohver

University of Western Ontario

Extraversion-introversion is the primary personality trait dimension in personality frameworks, from Eysenck's biologically-based three factors of personality to the five factor ("Big Five") taxonomy refined by Costa and McCrae to Lee and Ashton's six factor HEXACO model (Saklofske, Eysenck, Eysenck, Stelmack, & Revelle, 2012). Conceptualized as opposing poles along a single dimension, extraversion and introversion were seminally constructed by Swiss psychiatrist Carl Jung as distinct behavioral predispositions that are both normal and neutral in their adaptiveness. Extraversion is generally defined as the behavioral tendency to be bold and energized by high external activity and frequent interaction with other individuals, while introversion is the tendency to be energized by internal thoughts and personal exploration. Human research and animal models of introverted and extraverted behaviors support this construction, as both tendencies have been preserved in human populations, showing adaptive value in different environments. In mammalian species, introverted tendencies (e.g. quietness, caution) have been found to be more adaptive in changing or unstable environments – where sensitivity to stimuli is required – whereas extraverted tendencies (loudness and impulsivity) are more adaptive in stable environments, where sensitivity is not necessary. Therefore, for introversion and extraversion to be maximally adaptive and health-promoting, an individual's predisposition must complement their environment (see the work of eminent behavioral genetic and personality researcher Tom Bouchard; Frost et al., 2013).

Defining the Facets of Extraversion-Introversion

Despite its long history, the measurement of extraversion-introversion has recently been called into question due to problems in verifying the components (facets) that comprise the construct. Specifically, measures of extraversion-introversion differ in which facets are emphasized; sometimes extraversion-introversion is based more on assertiveness; sometimes energy and spontaneity; sometimes dominance, confidence, and agency; and

sometimes the tendency toward positive affect. Moreover, though high extraversion is often assumed to equate to sociability (the preference for social interaction), researchers have found that sociability is not a primary feature of extraversion, but rather the byproduct of other extraversion facets: social attention-seeking and pleasure from social interaction. In fact, the extraversion-introversion dimension has now been shown to be unrelated to the need for socializing and close relationships (Hofer, Busch, & Schneider, 2015).

Sensitivity to Stimuli and Arousal

Given its adaptiveness in unstable environments, introversion (low extraversion) is characterized by a heightened sensitivity to and processing of stimuli. Evolutionarily, there appears to be a large genetic effect involved in extraversion-introversion sensitivity predispositions. Highly extraverted and introverted individuals differ in brain cortex arousal, with highly introverted individuals displaying significantly greater baseline and post-stimulation cortical activity, particularly in the right brain hemisphere and vestibular and somatosensory brain regions (Schaefer, Heinze, & Rotte, 2012). Introversion is also positively related to brain-derived neurotrophic factor (BDNF) level, which promotes synaptic plasticity and neurotransmission in the brain. Interestingly, BDNF can interact with serotonin transmitters – the biological mechanism in the brain for generating positive affect and feelings of euphoria – in order to generate neurotic tendencies by suppressing serotonin (Terracciano et al., 2010). Facial recognition research also indicates that introversion promotes neurologic sensitivity to human facial expression when introversion is measured implicitly rather than through self-reporting. This supports Eysenck's theory that neurobiology is the primary underlying factor of variation in extraversion-introversion.

Interestingly, the extraversion side of extraversion-introversion does display a unique sensitivity to some specific stimuli; extraversion promotes sensitivity to reward stimuli – and insensitivity to punishment stimuli – as well as sensitivity in the brain's general approach system, encouraging approach behaviors. Approach behaviors are further reinforced by high extraversion's positive relations to thrill-seeking and need for stimulation, which is not shared by the introversion pole due to its pre-existing sensitivity.

Aggression, Dominance, and Sexuality

Though extraversion is a strong positive factor for a diversity of physical and psychological health concerns, it also possesses risks for a number of negative health effects. Specifically, extraversion is positively related to heightened testosterone, aggression, and social dominance. Subsequently, extraversion – particularly its assertiveness, sociability, and sensation-seeking facets – is a risk factor for several externalizing health problems such as hostility/anger, conduct and substance-use disorders, gambling, antisocial personality, and psychopathy (Mezquita et al., 2015). Extraversion also shows a modest relation to bipolar disorder. Interestingly, dominance through extraversion is supported by body type as well as testosterone levels, as current research indicates that more inhibited children typically grow up to adulthood with ectomorphic bodies and lower body mass indices compared to children with more extraverted tendencies, who possess a more mesomorphic physique.

Owing to the positive relations between extraversion and social aggression and androgen levels – and larger, more muscular bodies – extraversion also promotes sexual activity opportunity. More extraverted individuals show higher than average levels of sexual function and desire, as well as greater emphasis on sexual activity compared to introverted individuals, who demonstrate average sexual desire levels (Papageorgiou et al., 2012).

Positive Affect, Negative Affect, and Stress

Positive affect is a key characteristic of the extraversion pole of the extraversion-introversion dimension (Saklofske et al., 2012); along with other facets of extraversion – sociability/pleasure and assertiveness – it is negatively correlated with several internalizing problems, such as social anxiety, negative mood, long-term social dysfunction/phobia, and schizotypy (Watson, Naragon-Gainey, Watson, & Markon, 2009). Additionally, extraversion is positively related to adaptive coping strategies (e.g. problem-oriented coping, social support) to reduce the negative impacts of stress. Response to fear for high extraversion follows one of two affect patterns: rapid management of fear, if the individual places self-concept emphasis on being warm and active, or fear retention, if the individual emphasizes simple positive emotion and excitement-seeking (Pineles, Vogt, & Orr, 2009).

While introversion is positively associated with neuroticism, this is in part due to the dichotomization of introversion and extraversion along a single continuum (if high extraversion is negatively related with neuroticism, then high introversion must be positively related). Contemporary researchers note that definition matters, as the underlying preference for social interaction itself (not the derivation of pleasure from it) is not reliably related to morbidities, and need for social interaction is not related to extraversion-introversion at all. Therefore, researchers hold that introversion enhances pre-existing neurotic tendencies rather than creates them (see personality processes).

With this in mind, current research indicates that introversion – conflated with neuroticism – possesses moderate relations to social anxiety, negative mood, depression (when relation to neuroticism is not controlled for), self-blaming, and shame. Introversion is not significantly related to general anxiety, however. In terms of stress, introversion is related to greater vocal handicapping (inability to speak) following stress, though there is no relation to post-stress effort to vocalize. Similarly, individuals with more introverted tendencies require greater home-workplace separation to isolate work stress and achieve the same normal health functioning level as individuals with more extraverted tendencies (Baer, Jenkins, & Barber, 2016). Moreover, introversion appears to increase maladaptive coping strategy use, though this relation may be from conflated neuroticism (further work to determine this is required). Therefore, explicit definitional boundaries distinguishing extraversion-introversion and neuroticism are necessary to improve understanding of positive and negative affect relations.

Social Networks and Support

Though the need for and general appreciation of social interaction itself do not differ across the extraversion-introversion dimension (Hofer et al., 2015), the enhanced pleasure derived from it by more extraverted individuals – as well as the approach

behavior system and confidence – means extraversion thrives through social networks. Extraverted tendencies promote frequent interaction, leading networks to be overpopulated with highly extraverted individuals, disproportionate to the ratio of highly extraverted individuals in the general population. Additionally, due to a high extraversion presence network members are pushed toward inflating their own perceived extraversion level. Interestingly, extraversion is positively related to the tendency to self-present as more extraverted. This can be explained in part by the fact that while most individuals generally enjoy behaving in an extraverted manner in social situations, highly introverted individuals tend to perceive acting more extraverted as being draining and less beneficial than highly extraverted individuals (Zelenski, Santoro, & Whelan, 2012). Therefore, individuals within social networks usually possess a milder degree of extraverted tendency overall than is apparent during network interactions.

Dynamically, individual network research indicates that extraversion encourages large, homophilic (socially-similar) networks while introversion promotes small heterophilic networks. Additionally, high introversion results in qualitatively different kinds of friendships from high extraversion; extraversion emphasizes adventure, energy, power, talking, and relationship propulsion while introversion prioritizes stability and listening. Extraversion-introversion does not influence relationship closeness, though introverted tendencies do promote more gradual development of friendships.

Stability of Predisposition Over Time

While extraversion-introversion is a core personality trait, personality researchers have already shown that even very stable traits change over time, sometimes rapidly (see the work of eminent personality researcher Brent Roberts). Unsurprisingly, individuals typically show great variation in their extraversion-introversion tendency across their lifespan: individuals shift their state – hovering around their primary extraversion-introversion trait level – to suit situations. For example, extraversion level is negatively associated with age such that, in general, older individuals are less extraverted. Additionally, careers where heavy networking is required can encourage development of more extraverted tendencies (Lieneck & Nowicki, 2015).

Extraversion-Introversion: A Defining Factor

As the principal factor of personality, extraversion-introversion helps to define individuals' strengths, motivations, social preferences and behaviors, and health needs and risks. Analysis of particular facets of extraversion is generally recommended for understanding specific social behaviors – bypassing any facet emphasis problems of general extraversion-introversion measures – but the overall dimension provides a meaningful, biologically-driven explanation of social behavioral patterns across the lifespan.

Flow

Antonella Delle Fave[1] and Gaja Zager Kocjan[2]

[1] *University of Milano*
[2] *University of Ljubljana*

Flow, or optimal experience, is a highly complex and positive condition characterized by specific features at the cognitive, motivational, and emotional levels. As concerns cognition, flow includes intense and focused concentration, deep involvement, feeling of oneness with the ongoing task, and perceived control of the situation; at the motivational level, it comprises clear goals and autonomous behavior regulation that may reach the extreme pole of intrinsic motivation; affective features include loss of reflective self-consciousness and a global feeling of well-being. Flow-related activities are characterized by clear rules and structure, that allow individuals to retrieve clear feedback on the quality of their performance during the activity (Csikszentmihalyi, 1975/2000). The crucial antecedent of flow is the perception of high challenges in the ongoing activity, balanced with the perception of adequate skills to face them.

Studies conducted with both single administration instruments and real-time sampling procedures such as the Experience Sampling Method (ESM) repeatedly confirmed the experiential structure of flow and its global positivity, when compared with other experiences arising during daily life in relation to different combinations of perceived challenges and skills. This issue was specifically explored through the Experience Fluctuation Model (EFM; Massimini, Csikszentmihalyi, & Carli, 1987), designed to analyze the fluctuation pattern of daily experiences emerging from ESM data. In the model, the Cartesian plane is divided into eight channels, each representing a well-defined range of challenges/skills ratios, and corresponding to a specific experience. *Flow* is associated with the perception of moderate to high levels of both challenges and skills. When perceived skills exceed challenges, *relaxation* follows. Conversely, when perceived challenges exceed personal skills, *anxiety* is reported. The condition in which low values of both challenges and skills are perceived gives rise to the experience of *apathy*.

The intrinsic reward derived from the deep concentration, absorption and self-forgetfulness characterizing flow fosters the preferential replication of the associated activities. This process of long-term investment of personal resources on a specific subset of activities

among those available to individuals in their daily social context was defined as psychological selection (Massimini & Delle Fave, 2000). Two major dimensions orient this dynamic process. The first one is related to the activity potential for complexity. As people develop progressively higher skills through repeated activity performance, in order to continue experiencing flow they must engage in gradually higher challenges, otherwise boredom could arise. The search for ever increasing challenges and the related skill refinement generate a virtuous cycle that promotes progressive learning and personal growth, supporting individuals' active building of their own life trajectory. The second dimension orienting psychological selection is the meaning and relevance of flow-related activities for the person and the social context, in the light of the values and priorities endorsed by individuals and their culture. In order for flow activities and psychological selection to promote authentic personal growth, they should favor both increasing skill complexity and meaning-making. While simple tasks are structurally inadequate to promote skill enhancement, highly structured tasks devoid of adaptive meaning (as often happens with attention-consuming but futile leisure, or antisocial activities such as pickpocketing) may indeed facilitate flow, but they do not promote adaptive growth and complexity (Nakamura & Csikszentmihalyi, 2009).

The Phenomenology of Flow in Daily Life

Several studies showed that people across the most diverse cultures, health and socio-economic conditions, life stages, and occupations report flow in their life and describe it as a positive and rewarding experience. However, investigation of the psychological features of flow with ESM across samples and activities showed that, while cognitive components represent a stable core of this experience, affective and motivational ones vary across activities. Specifically, productive activities such as work and studying are associated with lower values of positive affect and self-determination, while perceived goals are above-average. The reversed pattern, with higher positive affect, intrinsic motivation, and below-average goals, usually characterizes structured leisure activities, such as sports or hobbies (Delle Fave & Massimini, 2005). These findings suggest the existence of a "family" of optimal experiences, whose emotional and motivational features vary depending on the associated activities.

Individual Factors Promoting Flow

While demographic variables such as gender, age, culture, education, socio-economic status, and health conditions have little impact on the individual potential to attain flow and on the psychological features of this experience, they do influence the frequency of flow occurrence and the typology of associated activities. For example, women associate flow with social interactions more frequently than men, who instead more often refer to sports. Biological dispositions and talents in specific domains were found to support both flow retrieval in these domains during adolescence, and academic and professional investment them in the long term. Acquired physical impairments leading to disability were shown to restrain access to previously practiced flow

activities, at the same time highlighting the human ability to identify new flow activities compatible with the disability condition.

Researchers have also investigated the relationship between flow and personality. Csikszentmihalyi described the *autotelic personality* as a constellation of specific psychological features that make some people more prone to experience flow. Autotelic people engage in activities for their own sake, rather than to achieve some external goal, and they actively seek environmental challenges that are adequate to their skills. They possess further "meta-skills" including curiosity and interest, persistence, and low self-centeredness. In a study conducted among Japanese college students (Asakawa, 2010), autotelic participants reported better quality of daily experience, higher sense of fulfillment and satisfaction with life, higher self-esteem, lower anxiety and more active coping strategies than the other students. A specific measure of autotelic personality, based on Csikzentmihalyi's conceptualization, was recently developed and validated (Tse et al., 2018).

Researchers have also investigated which personality traits among the Big Five factors are associated with proneness to experience particularly intense levels of flow (Ross & Keiser, 2014; Ullen et al., 2012), finding that high-intensity flow was positively associated with conscientiousness and negatively with neuroticism. Other studies instead measured the relationship between personality traits and the occurrence of flow. Only openness to experience was a significant predictor of flow onset (Bassi, Steca, Monzani, Greco, & Delle Fave, 2014). Taken together, these findings are consistent with the distinction between receptive and active qualities proposed by Cskszentmihalyi as regards personality traits associated with flow. Openness to experience, a receptive quality related to curiosity and susceptibility to new challenges, fosters the identification of flow opportunities. Active qualities such as low neuroticism and high conscientiousness support the duration and intensity of flow after its onset. While emotional instability, negative affect, and high self-consciousness characterizing neuroticism may interfere with the flow experience, the control, self-discipline, and willpower characterizing conscientiousness foster concentration and deliberate engagement in flow-related tasks. No relationship was detected between personality factors and typology of flow activities individuals preferentially engage in.

In addition to personality dimensions, other trait-like factors were examined in relation to flow. Positive associations were detected between flow and self-esteem, optimism, self-efficacy beliefs, achievement orientation, intrinsic motivation orientation, internal locus of control and, as previously described, meaning attributions.

Social and Cultural Factors Related to Flow

Beyond personal characteristics, differences related to social and cultural features may influence the frequency of flow experiences as well as the variety and typology of related activities. As a macro environment characterized by specific norms, values, and habits, culture orients the process of psychological selection. Contexts favoring an individual's autonomy and ability to exert concentration have greater potential to foster flow retrieval in daily life and long-term commitment to related activities. In addition, different cultures promote selective resource investment in different life domains and activity types, based on their values, structure, and organization. At the meso-level of institutions, the work context may promote or prevent

flow onset. In industrial and post-industrial societies a wide range of occupations are characterized by high automation and repetitive tasks, low in meaning and complexity and thus failing to provide challenges adequately high to support flow onset. Workers enrolled in these jobs prominently retrieve flow in leisure or social relationships. Conversely, work contexts offering employment opportunities in more autonomous, self-expressive, and challenging work tasks, including arts, science, helping professions as well as traditional jobs and crafts that were recently rediscovered in Western countries, providing individuals with high challenges and complexity that altogether favor flow. At the micro-environmental level, the family influences individuals' selective engagement in flow-related activities (Rathunde, 2001). Parents can foster children's positive development by exposing them to meaningful and structured activities in which they can invest attention and refine skills, and by providing them with challenging objectives as well as adequate support toward their achievement. In addition, parents' self-efficacy beliefs and self-determination levels concur in promoting children's exposure to and cultivation of flow activities. Overall, the quality of family interaction patterns may foster or hinder all family members' potential for experiencing flow.

Future Directions

Despite researchers' efforts, flow proneness is still an unclear construct, requiring further conceptual and empirical investigation. Moreover, since the vast majority of people around the world report flow experiences regardless of their personality features, flow antecedents seem to extend beyond personality, including family, social, and cultural factors. These factors contribute to the selection and transmission of activities high in flow potential, and to the shaping of a supportive and challenging environment in which flow is more likely to occur.

Gender Differences in Aggression

Jessica K. Padgett and Paul F. Tremblay

University of Western Ontario

Different Types of Aggression

At its most general level, aggression consists of behavior intended to harm someone else, and violence consists of aggression intended to cause extreme harm. Aggression can occur in reaction to provocation or it can be premeditated. Aggressive behavior can also be categorized as either direct or indirect. Direct aggression includes verbal, physical, and sexual actions perpetrated overtly and directly with the victim present. Indirect aggression, on the other hand, consists of covert and sometimes more subtle actions perpetrated often without face-to-face contact, thus permitting the offender to remain anonymous. Indirect aggression includes actions such as spreading rumors, damaging property, or social ostracism. Relational aggression is a specific type of indirect aggression that involves damaging peer relationships. With the advent of social networking, indirect aggression has increased dramatically and captured the attention of researchers. Males and females often differ in the types of aggression that they are more likely to use.

Gender Differences Throughout Developmental Stages

Throughout the lifespan, males are more likely than females to engage in physically aggressive or violent behavior, and they are also more likely to be the victims of such actions. An extensive longitudinal research program by R. Tremblay and colleagues (e.g. Baillargeon et al., 2007) has revealed that males show a higher level of physical aggression than females do. This begins in the second year of life with behaviors such as grabbing toys from another child, followed by hitting another child later on. Physical aggression tends to peak from the age of two to four, but while most children learn not to use physical aggressive behavior by that stage, a small proportion of children, mainly boys, develop severe forms of aggression.

Severe physical aggression is mostly perpetrated by men and often emerges in adolescence, peaks in the late teens or early twenties and begins to decrease in the mid or late twenties

(Archer, 2004). Almost all cases of sexual assault and rape are perpetrated by men, and females are more likely than males to be the victims. Gender differences in verbal aggression are less prominent than with physical aggression, and the research has been inconsistent, finding minor differences in both directions.

The transition from direct aggression to indirect aggression is common among both boys and girls, but the trajectories are somewhat different. Females use more indirect forms of aggression than males do, beginning just before the school years. This difference widens in adolescence and then narrows and disappears in early adulthood.

Among heterosexual couples, men and women report engaging in physical aggression with equal frequency but men are more likely to injure their partner by beating, choking, or strangling them. Women are more likely to use retaliatory aggression than to initiate aggression. A typical feature of aggression in intimate relationships is its repetitiveness because the environment often remains relatively stable (i.e. one's home). Research has shown an important connection between aggression in intimate relationships and heavy alcohol consumption.

Male-to-Male vs. Male-to-Female Aggression: The Barroom Setting as an Example

The social context and the nature of the conflict influence gender differences in aggression. One interesting setting is the barroom where physical aggression tends to occur between males and aggression of a sexual nature is used by men on women. In both cases, alcohol can play an important role for both perpetrators and victims, exacerbating the aggression and likelihood of negative consequences. Much of the research on aggression in bars comes from extensive observation research by Graham and colleagues (e.g. Graham et al., 2013). That research has revealed that men are likely to be the initiators of aggressive sexual overtures and intimidation, whereas women mostly react to provocation, such as resisting aggressively and expressing anger with body language. The aggression that occurs between men in bars has been linked to the need to maintain a macho image and competition for women.

The Role of Provocation

Aggression often occurs in reaction to some form of provocation but males and females differ in what will provoke them to retaliate. For example, among heterosexual couples, men are provoked more by sexual infidelity while women are provoked more by emotional infidelity. A classic meta-analysis by Bettencourt and Miller (1996) revealed that with the introduction of provocation, females were just as likely as males to act aggressively. However, in situations where women feared retaliation, they were less likely to engage in aggression. In general, males do not necessarily require much provocation to engage in physical aggression with strangers, whereas women are much more cautious and sensitive to danger, especially when the opponent is a physically threatening stranger. Men are higher risk takers and may feel they have more to lose than women do in terms of maintaining a specific identity of toughness, especially in the presence of their friends.

Attitudes and Beliefs About Aggression

One way of explaining the strong gender differences in aggression is to look at the differences in how men and women think about aggressive behavior. One supported theory is that women hold an "expressive social representation" that aggression is a loss of self-control, whereas males hold an "instrumental representation" that aggression is a means of imposing control over others (Campbell & Muncer, 1994). This said, both men and women find violence against women less morally acceptable than violence against men. Males can often see positive instrumental consequences of their aggression when it is used to protect their honor and masculine image. However, masculinity itself is a complicated and changeable aspect that often varies across time, culture, class, and race. Historically, masculinity has been linked to violence, often an excusable and even expected reaction to threats to one's honor. Yet, even though the idea that violence is a necessity of masculinity has waned over recent times (beginning in the Victorian era when a gentleman was expected to preserve self-control, violence being an action for working class men), the legacy of aggression as a central trait of masculinity still lingers today (Whitlock, 2014).

Evolutionary and Biological Explanations of the Gender Differences

The higher rate and severity of physical aggression among males may have resulted over evolutionary history, which has produced different sexual reproduction strategies for males and females. Sexual selection is a process in which males compete for mating privileges, whereas females choose between potential mates. Variation in reproductive success is much greater for males than for females, with a relatively select group of stronger males having greater access to mating. Hence, males engage in greater and more dangerous competition (i.e. male-to-male aggression and violence) than females out of reproductive necessity. In terms of reproductive success, females make a stronger parental investment with a nine-month gestation period and subsequent care and nursing, whereas males' reproductive success depends on mating with as many females as possible. Furthermore, while a female can have no doubt that she is the mother of her child, the best way for a male to ensure reproductive success is to have a high insemination rate. Evolutionary psychologists test these hypotheses by investigating such things as gender differences in preferences for more partners in contemporary society. The evidence tends to be mixed.

Another way to explain greater aggression in males is to look at biological factors that influence aggressive behavior. There has been considerable research on the moderating role of testosterone in gender differences of aggression but no clear pattern has emerged. Research on specific genes and neurotransmitters has been linked to aggression but again this research is limited. One common biological trait that has been associated with antisocial behavior is low autonomic arousal, a feature which is more common in males as they have a lower resting heart rate.

Social Role, Learning, and Socialization

Social role theory proposes that differences in size and physical strength between men and women and women's capacity to bear children have historically contributed to different positions in labor and society (see Eagly & Steffen, 1986). As a result, men have held more positions of power and status, and this has led to more dominant behavior by men. Traditionally, men have been more likely to adopt roles in the military and high status competitive positions, while women have cared for children or adopted caring and nurturance dominated jobs such as nursing and teaching. These different roles reinforced attitudes of power and can further influence aggressive attitudes and behaviors.

Social learning theory suggests that aggression can be learned by direct experience or through observation and can be transmitted through various modes from one generation to the next, through peers, through the media, and more generally through cultural values. Boys are socialized to be tough and to defend themselves physically, whereas girls are taught to keep out of harm's way. The widespread violent entertainment media can support and propagate these gender roles. The role of violent media in aggression has been studied extensively and the evidence does suggest an effect.

Males tend to be exposed to more environmental risk factors that lead to antisocial and physically aggressive behavior. For example, they are more likely to have peers who participate in antisocial behavior and are more likely to receive harsher physical punishment from parents. Throughout the lifespan, the differences that males and females experience in their personal relationships may also be influential. For example, parents often monitor their daughters more closely than their sons which might cause girls to be more likely to inhibit aggressive behavior.

Directions for Future Research

Studying gender differences in aggression provides some clues for improving gender specific prevention and intervention programs. The contemporary example of cyber bullying reminds us that as society evolves, psychological individual differences manifest themselves in new ways and therefore require a continual research commitment. There has been some research into the link between gender differences in aggression and in neurodevelopment, specifically interhemispheric communication and brain maturation as expressed with earlier cognitive and learning deficits in boys. This is an area that will no doubt develop further with advances in school psychology and cognitive neuroscience.

Gender Differences in Perceived Traits of Men and Women

Emily R. Bunnett

Swinburne University of Technology

An abundance of literature and empirical research has investigated the presence of personality traits and the main factors on which comparisons between individuals can be made. That is, personality is often conceptualized as the degree to which an individual portrays particular traits, with traits being defined as consistently exhibited patterns of thoughts, feelings, motives and behaviors that are displayed across contexts (Weisberg, DeYoung, & Hirsh, 2011). Through extensive factor analyses over varied studies and research methodologies comprising all potential descriptive adjectives pertaining to one's personality, the widely known and employed Five Factor Model (FFM) or Big Five has been identified and enabled an overarching, hierarchical framework on which previous findings may be mapped and compared. Specifically, the broad five factors comprise Extraversion, Openness to Experience, Agreeableness, Conscientiousness and Neuroticism, and each of these comprehensive factors exhibits a number of more specific facets (please see Gosling, Rentfrow, & Swann Jr., 2003 for a detailed presentation of the underlying facets). Gender differences in personality, perceived personality, and stereotypes, therefore, generally describe the relative standing of each gender on these factors and facets, on average. Nevertheless, while an abundance of literature has only indicated small to moderate gender differences in the Big Five factors, the amount of research into gender differences on the underlying facets, and even more so on the perceived gender differences in personality, is far less pervasive. The current entry will outline the perceived gender differences in traits of men and women and the variations in gender stereotypes, followed by those that are empirically found across cultures, ages, ethnicity, and assessment methods, and an explanation of the most prevailing theories employed to describe the patterns of results obtained.

Self-Report and Observer Ratings of Men's and Women's Personalities

In general, women tend to score higher on neuroticism and agreeableness than men. They also tend to score higher than men on conscientiousness, openness, and extraversion, however, these differences tend to be smaller and are inconsistently evidenced across studies, which may reflect the more gender disparate effects at the facet level (Löckenhoff et al., 2014). Weisberg et al. (2011) suggest that one way of synthesizing the extent of analyses required to run a full facet level approach to revealing gender differences in personality is to view the two aspects that have been found to underlie each factor. Specifically, each Big Five factor comprises two correlated yet discrete aspects that provide a description of personality below the factor level yet above that of the facets. Gender differences on each broad factor and their underlying aspects and facets will be discussed briefly, in turn, below.

Neuroticism

Embodies the tendency to experience negative emotions such as anxiety, anger, self-consciousness, emotional lability and depression and to exhibit a low tolerance of stress and aversive stimuli. In general, women tend to score higher on all facets of neuroticism, however, men often score higher on the order facet anger, the expression of which is also more commonly considered acceptable when displayed by men. The two aspects of neuroticism are withdrawal and volatility. Women tend to score higher on both, until the shared variance between the two is canceled out through assessing gender differences in the regression residual values. Specifically, when the withdrawal is held constant, there is no significant difference in volatility between the genders, whereas, when volatility is held statistically constant, the mean score for women remains, on average, statistically greater than that of men. This pattern of results may be seen as while women tend to score higher on anxiety, vulnerability, depression, and self-consciousness, which are facets that incorporate the aspect of withdrawal, volatility describes the tendency to easily display acts of anger and irritability, which are more common in men.

Agreeableness

This trait reflects the degree to which one seeks to find and exhibit harmony with others. It includes traits such as altruism, kindness, co-operation, empathy, tender mindedness and consideration of others. Women tend to score higher on the overall factor and all facets of agreeableness, including the two aspects compassion and politeness. Gender differences on this factor may reflect differences in self-construal, women tending toward a more interdependent self-construal and males a more independent sense of self; that is, women may be more motivated to display and maintain social and emotional bonds with others than men.

Conscientiousness

Conscientiousness describes the degree to which one acts dutifully and shows self-discipline, self-control, rule following, and motivation to strive for achievement and goal attainment despite any potential extraneous stressors. While some studies have evidenced small

significant differences, with women tending to score higher than men on conscientiousness, this result has been inconsistently found given the disparate gender differences displayed on the facet and aspect level. In particular, conscientiousness may be divided into the two more specific aspects of orderliness and industriousness, with women often scoring higher on the former and men the latter, especially when the effects of the other aspect are canceled out through regressing one onto the other.

Extraversion

Extraverts frequently enjoy the company of other people, being the life of the party and also tend to be assertive. Gender differences at the factor level tend to display a rather small effect size, with women tending to exhibit greater extraversion overall than men. This small effect size and the inconsistency in previous results may be due to the discrete gender differences that are apparent at the facet level of personality; women tend to score higher on gregariousness, warmth and positivity and men on excitement seeking and assertiveness. Furthermore, the variation in the size and significance of gender differences in extraversion may also be explained in terms of the underlying aspects, enthusiasm and assertiveness. Women generally score higher on the traits of enthusiasm (i.e. sociability, experience of positive emotions, and gregariousness), whereas men commonly score higher on the facets associated with assertiveness (i.e. excitement seeking, agency, and dominance).

Openness

People who score high on openness tend to display a general appreciation of art, emotion, adventure, imagination, creativity, curiosity and being open to new and varied experiences. Broadly this factor also reflects the ability and interest in attending to and processing complex stimuli; that is, people who are open to experience tend to be intellectually curious. While significant gender differences are not commonly found on this factor, several studies have evidenced small differences, with women tending to score higher than men. These disparate findings are likely reflective of the divergent facets that underlie this concept. Specifically, women tend to score higher on the feelings and esthetics based facets, whereas men commonly achieve greater scores on the openness to ideas facet. This proposition is supported by analyses at the aspect level, with women scoring higher on openness and men on intellect.

Perceived Gender Differences and Gender Stereotypes

Much less research has been conducted into the degree to which gender stereotypes and perceived gender differences mirror the aforementioned findings of gender differences in the Big Five. This is particularly important as gender stereotypes tend to be highly prescriptive; that is, they denote the behaviors and traits that are expected be displayed by women and men, individually (Prentice & Carranza, 2002). Men tend to be perceived as higher on agentic and instrumental traits, while women are commonly perceived as presenting higher degrees of nurturing and communal traits. Nevertheless, findings tend to be fairly

inconsistent, with some indicating that women are perceived as scoring higher on agreeableness and neuroticism, yet lower on extraversion, conscientiousness, and openness. These findings are somewhat contradictory to the abovementioned gender differences that are reported through self-report and observer ratings. Conversely, others have reported that women tend to be perceived as scoring higher on agreeableness, conscientiousness, and openness than men, yet similar to them on extraversion and neuroticism. Similarly, Löckenhoff et al. (2014) reported that women were rated higher on all Big Five factors, except extraversion, with this effect being most pronounced for agreeableness. Furthermore, while investigations at the facet level were consistent with those at the factor level for agreeableness, openness, and conscientiousness, ratings at the facet level were more mixed for neuroticism and extraversion. With regard to extraversion, women were rated higher than men on warmth and positive emotions and lower on excitement seeking and positive emotions; the remaining facets were rated as fairly equally prevalent in both genders. Moreover, women were rated as higher on the neuroticism facets of anxiety and vulnerability and lower on impulsiveness than men. These findings were also rather consistent with the self and other ratings of actual gender differences evidenced in this study. Further research needs to be conducted into assessing the perceived gender differences on the Big Five factors and the underlying aspects and facets of these factors, as well as the degree to which they map onto the empirically derived gender differences.

Theoretical Models and Consistency across Cultures, Ages, Ethnicity, and Testing Methodology

Several general theories have been proposed to explain the gender effects seen regarding personality and perceived differences across personalities. The biological theory proposes that women and men exhibit different personalities due to their innate differences and tendencies toward caring for young and successfully gathering resources (evolutionarily and biologically the role given to females) versus becoming strong, protective hunters (consistent with the traditional role and characteristics of males). Specifically, biological theories suggest that gender differences in personality arise through innate, evolved differences between men and women. Further biological theories have postulated that hormonal differences may play a role in the differences found between genders in personality.

Conversely, social role theories suggest that such differences arise due to different roles that women and men play in society, being aligned with those they are expected to exhibit. Alternative, sociocultural theories have focused on the artifacts of testing (i.e. participants report higher levels of the traits that are seen as more socially desirable for their gender) and the effect of frame of reference (whether people rate themselves relative to all individuals or only those within the same gender).

Gender differences in self and other rated personality traits and perceived gender differences in personality have been found to be consistent across most cultures, age groups, and ethnicity. Nevertheless, these differences appear to be of lesser magnitude in Eastern cultures, than Western cultures, which may partially discredit the social role theory, as it is expected that Eastern cultures would show more traditional social roles and hence greater differences in the perceived and actual differences in personality across genders.

Nonetheless, it may be argued that a combination of biological and social role theories is responsible for these findings. Specifically, sociocultural differences (e.g. gender stereotyping, gender equality, and socio-economic contexts) may mediate the effect of social roles. Furthermore, the pervasive nature of gender differences is in line with biological theories, yet this theory is unable to explain the existence of varied magnitudes across cultures. However, it is important to note that previous findings may reflect socially desirable responding, as testing methodology has been found to significantly mediate the responses participants provide. Specifically, males and females both tend to rate themselves more positively when completing paper-and-pencil questionnaires in laboratory settings, yet less favorably when doing so online, which is hence expected to provide participants with a greater sense of anonymity and security (Feingold, 1994). Taken together, the findings to date therefore suggest that a biosocial model may best explain previous findings, however, future research should be conducted to further delineate the exact role that each of the bases for various theories plays in the actual and perceived presence of differences in personality across genders.

Gender Differences in Self-esteem and Self-confidence

Silvia Casale

University of Florence, Italy

Definition of Self-esteem and Self-confidence

Self-esteem has held a central place in the scholarly and popular understanding of the human being since the last decades of the nineteenth century. Social scientists have defined self-esteem in at least three different ways, each of which has stimulated meaningful research and given rise to entire schools of thought on the topic over time.

The first definition was crafted by William James (1890), who described self-esteem as a ratio or relationship between one's own achievements and one's own aspirations by saying "Our self-feeling in this world depends entirely on what we back ourselves to be and do. It is determined by the ratio of our actualities to our supposed potentialities, a fraction of which our pretentions are the denominator and the numerator our success" (p. 296). Works that stem from James's definition tend to focus on behavioral outcomes and the discrepancies between one's ideal self and the real self. Stressing a certain type of behavior rather than affect, attitude, or belief, and arguing that people draw self-esteem from accomplishments in certain areas, leads, as a result, to an overlap between the construct of self-esteem and that of self-confidence.

A different definition of self-esteem has been given by Morris Rosenberg, who said "self-esteem, as noted, is a positive or negative attitude toward a particular object, namely, the self" (1965, p. 60). Such an attitude is thought to be based on the perception of a feeling about one's "worth" or value as a person. Whereas James's definition defines the construct in terms of successful or competent action, thus stressing the behavioral aspects, Rosenberg has defined self-esteem mainly as an internal phenomenon – as an attitude, belief, or feeling.

The third and final approach to self-esteem conceptualizes it as a more complex phenomenon consisting of both behavioral dimensions and internal phenomena. Nathaniel Branden (1969, p. 110) stated that "self-esteem has two interrelated aspects: it entails a sense of personal efficacy and a sense of personal worth. It is the integrated sum of self-confidence and self-respect."

Current definitions also vary as to whether they focus on self-esteem as a relatively unchanging stable trait or as a situational phenomenon. Some conceptualizations define self-esteem as being reasonably stable over time, whereas others regard self-esteem as a relatively transitory process that fluctuates in response to situational and contextual stimuli. Meta-analyses tend to support the stability perspective by showing that the stability of self-esteem across all age groups is comparable to that of the major higher-order personality dimensions.

Current definitions also vary depending on what is the focus of the subjective evaluation. Global self-esteem has been defined as either the positivity of the person's evaluation or the level of global regard that one has for the self as a person. Domain-specific self-esteem describes self-confidence in specific areas (e.g. appearance, academics, or social situations). Although self-esteem and self-confidence are distinct concepts, domain-specific self-esteem has an important overlap with self-confidence because it addresses confidence in certain areas of competence. As a consequence, the term self-confidence is often used to describe the process by which people evaluate their various abilities and attributes. Terms such as "self-evaluation" and "self-appraisal" are generally preferred to "self-confidence" because they refer to the way people evaluate or appraise various aspects of the self in a more specific manner.

Gender Differences in Self-esteem and Self-confidence

Some of the best-established findings in the self-esteem literature concern gender differences, which have been systematically examined since the 1990s. Meta-analytic studies (Gentile, Grabe, Dolan-Pascoe, Twenge, & Wells, 2009; Kling, Hyde, Showers, & Buswell, 1999; Major, Barr, Zubek, & Babey, 1999; Twenge & Campbell, 2001) have provided robust evidence that a gender gap exists – that men tend to have higher self-esteem than women. This gender gap emerges in adolescence and persists throughout early and middle adulthood before it narrows in old age. The reported effect size typically ranges from small to medium during all stages of life except adolescence, when it tends to become modestly larger.

This gender gap notwithstanding, a robust finding to emerge from meta-analytic studies is that both men and women seem to follow essentially the same life span normative trajectories throughout the life cycle: for both genders, self-esteem is relatively high in childhood, drops during adolescence, tends to increase during the transition to adulthood, and then declines in old age. These results indicate that self-esteem shows remarkable continuity for both genders, despite the vast array of experiences that an individual faces during his or her lifespan. At the same time, however, these findings reveal systematic changes that might be associated to age-related experiences and contexts. As with the gender differences discussed earlier, the effect size for age-graded increases in self-esteem levels during adulthood falls within the range of small to medium.

It has also been suggested that global self-esteem assessment might mask important gender differences in particular components of the self-evaluation process. Higher self-evaluations (i.e. higher self-confidence) among men in some areas might be balanced by higher self-evaluations among women in other areas. When specific domains of self-esteem have been

the focus of meta-analytic studies, it was found that gender differences vary widely across sub-domains of self-esteem. Men tend to score significantly higher than women on physical appearance, athletic, personal self, and self-satisfaction self-esteem, while women scored higher than men on behavioral conduct and moral-ethics self-esteem. No significant gender differences appeared in social acceptance, family, and affect self-esteem, and the gender difference in physical appearance self-esteem was significant only after 1980, particularly among adults. Although many of the gender differences in specific domains of self-esteem are considerably larger than the differences highlighted in global self-esteem, the gender gap as it relates to domain-specific self-esteem is not substantial.

Research has also examined self-esteem formation by focusing on gender differences in source importance (Schwalbe & Staples, 1991). The relative importance among men and women of reflected appraisal, self-perceptions, and social comparisons as sources of information about the self has received growing attention in recent years. Research supports the notion that women attach more importance to reflected appraisal than men, and that men attach more importance to social comparison than women, whereas no significant differences were found regarding the importance attached to self-perceived competence. An overall pattern of gender similarities also emerged because reflected appraisals are often cited as the most important source of self-esteem among both genders, followed by self-perceived competence and social comparison.

Cross-cultural Considerations of Gender Differences in Self-esteem

The vast majority of empirical studies that have examined gender differences in self-esteem have focused on the United States and other Western industrialized nations. Recent scholars have begun testing whether the widely reported gender and age differences in self-esteem are cross-cultural universals or culture-specific phenomena. Although certain cultures seem to differ in terms of the magnitude of the gender gap, cross-cultural examination supports claims of broad cross-cultural similarities, as men consistently reported higher self-esteem than women. Moreover, age-related increases from late adolescence to middle adulthood have also been found among both genders. The average effect sizes for gender and age ranged from small to medium, thus reinforcing previous research on this topic. As a whole, these results suggest that gender and age differences are driven, at least in part, by universal mechanisms that reflect both universal sociocultural factors and genetically-based biological processes that transcend culture and context (Bleidorn et al., 2016).

Scientific Explanations of Gender Differences in Self-esteem and Self-confidence

Explanations for gender differences in self-esteem levels tend to focus on either maturational changes associated with puberty or social-contextual factors associated with the different expectations women and men face throughout all stages of the life cycle. Although no generally accepted integrative theoretical models exist, two theoretical approaches have

tried to explain the gender gap in self-esteem and self-confidence levels. For instance, some biological theorists argue that gender differences arise from innate temperamental differences between the sexes that came about through the process of natural selection. Evolutionary psychologists have argued that men and women differ in specific domains because they have faced different adaptive problems throughout evolutionary history. Social psychological theorists, on the other hand, argue for more proximal and distal causes of gender differences in self-esteem and self-confidence. According to the social role model, gender differences are a consequence of adopting gender roles that define appropriate and socially accepted conduct for men and women. It is worth noting, however, that explanations derived from biological and social psychological theories are not necessarily mutually exclusive, as social roles can sometimes modify biologically-based patterns (Costa, Terracciano, & McCrae, 2001).

Gender Differences in Subjective Well-Being

Naomi L. Perry

Swinburne University of Technology, Melbourne, Australia

Introduction and Overview

Subjective well-being (SWB) is a positive psychological characteristic that is associated with happiness, life satisfaction, and mental health, whilst being negatively correlated with mental health disorders such as depression and anxiety. SWB consists of both cognitive and emotional evaluations about one's own life. The emotional component encompasses moods (positive and negative), whilst the cognitive component consists of an evaluation of one's own satisfaction with different aspects of life. The cognitive component is therefore influenced by an individual's outlook and their perception of what constitutes a "good life." Subjective well-being is therefore a very broad concept including, but not limited to, the experience of positive emotions, absence or low levels of negative emotions, and high life satisfaction. An individual's subjective well-being is largely stable over time, and whilst setbacks or gains may have a temporary effect, the individual eventually returns to their "baseline."

The relationship between gender and subjective well-being is not straightforward. Some decades ago the subjective well-being of women was consistently higher than that of men. In more recent times, the subjective well-being of women appears to have steadily decreased. Women have greater rates of negative affect, as well as lower rates of life satisfaction and positive affect in comparison to men in Western countries. The prevalence of mental illnesses such as depression and anxiety is also much higher in females than in males across the lifespan, especially in high-income countries.

Research suggests that women may only be more satisfied with their lives when they are placed in similar circumstances to men, therefore the cognitive component of subjective well-being may be higher in females than males. However, the emotional component appears to be higher in males than in females. On the other hand, several studies have reported very little difference between males and females in terms of life satisfaction and happiness. This may be due to the notion that although women are more satisfied when in the same circumstances as men, generally women live in worse conditions than men which

may mask this effect. Certain factors such as age and other demographic variables may also conceal gender effects if not taken into account.

Gender Differences in Subjective Well-Being Across the Lifespan

Although a good deal of research shows little difference in SWB between males and females, it has been argued that any difference has been masked by an interaction effect between age, gender, and well-being. During childhood and adolescence, males are not only less likely to develop anxiety or depression; they are also more likely to report higher levels of subjective well-being than females. This continues up until the age of about 18 years, at which point females begin to experience higher levels of subjective well-being than males.

Before the age of 45, women in high-income countries show modest increases in SWB compared with men, which may be due to advances in terms of gender equality in these societies. In lower income countries, there is little difference between genders in younger adults. However, whilst women in early to mid-adulthood may have similar or even higher SWB compared with men, older women tend to report lower SWB than their male counterparts, particularly in industrialized countries. This gender difference increases into old age, such that the largest gender gap is observed in very old samples.

The decline in SWB in older women in developed countries has been explained in terms of the devaluation of the social worth of older females. In these countries, the media and society as a whole place an emphasis on beauty and attractiveness in women being associated with youth, whilst older males are still depicted as being attractive due to their power and experience. An alternative explanation is that although women tend to live longer than men, they also experience more years of illness or disability. Subjective well-being is correlated with physical health, therefore living in poorer health may contribute to lower SWB. With the increasing aging population seen in many industrialized countries, the number of females experiencing a decline in SWB may well be on the rise.

Cultural Influences on Gender Differences in Subjective Well-Being

The majority of literature regarding gender differences in well-being comes from the United States and Western European countries, however there is increasing interest in cross-cultural studies in this area. Findings from these studies show that gender differences in SWB are not identical across all countries, and whilst women report slightly lower SWB than men in some countries, they report slightly higher SWB in other countries. It has been reported that in most countries women are actually happier and more satisfied than men. Overall, it appears that females report higher SWB in developing countries, such as African countries, whilst in industrialized societies such as the United States and European countries, females report lower SWB than males. Thus, it may be the wealth of research conducted in developed countries that has led some researchers to conclude that women have lower SWB than men.

One explanation for these cross-cultural differences centers on gender inequality. As gender inequality varies across countries, so too does the difference in ratings of well-being between males and females. Generally, the greater the gender inequality of a country, the larger the gender difference in SWB is. However, this effect depends on the cultural acceptance of gender inequality. In countries where equality is favored, differences in SWB decrease where there is equality for both genders in the labor market. Conversely, in countries where gender inequality in the labor market is accepted, gender differences in SWB increase as women's equality in the workplace increases. Thus, gender inequality appears to play an important role in the relationship between gender and SWB.

Other factors may also explain the differential effects of country-level conditions on male and female well-being. The political climate of the country and the predominant religion, for instance, are thought to have strong effects. A history of communism is associated with poorer outcomes for females, whilst political freedom raises SWB for males more than for females. In terms of religion, females report higher SWB in comparison to men in countries with a high percentage of Muslims, whilst the opposite is found in countries with a high percentage of Catholics.

Putative Explanations for Gender Differences in Subjective Well-Being

It has been suggested that gender differences in subjective well-being may be due to biological causes, in particular hormonal effects. Indeed, hormonal fluctuations across the menstrual cycle and postpartum are linked with increased negative affect and depression. However, gender differences in SWB cannot be fully explained by biological roots. Since the pattern varies across countries, it is far more likely that there is a social explanation for these differences.

One such social explanation for these gender differences is that males and females are exposed to different living conditions. In many societies women have reduced access to resources (such as income), opportunities (e.g. in the workforce), and power (e.g. being underrepresented in parliament). These disadvantages may underlie the gender differences in SWB by contributing to the unhappiness and reduced life satisfaction seen in females. Subjective well-being depends on the ability of an individual to reach their goals and achieve their ambitions, therefore as females have a reduced potential for pursuing goals they are often less successful in reaching them. This may also explain the cross-cultural differences as the goals of women in countries where gender inequality is accepted may be different from those in industrialized countries and therefore those women may not experience a reduced potential for achieving those goals.

On the other hand, research shows that females actually experienced higher SWB than males up until the early to mid-1980s. It is since the late 1990s that this pattern has changed, with women now reporting reduced life satisfaction compared with men in advanced industrial societies. Given the increase in gender equality over these years, the above explanation for lower female SWB does not explain this shift in subjective experience. Several studies have also found that income, education, and occupation explain surprisingly little of the variation between genders in SWB. An alternative view is that it is the *expectation* of gender

equality and female employment that is detrimental to SWB. In developing countries, there is less expectation placed on women, therefore SWB is higher.

A final explanation for gender differences in SWB comes from differences in personality traits. In self-reports, males tend to show higher levels of extraversion, conscientiousness and openness to experience, whilst females report higher levels of neuroticism and agreeableness. Research has shown that controlling for neuroticism and extraversion eliminates any gender difference in SWB, suggesting that personality traits may play a role in SWB.

Future Directions for Research

The majority of research to date has focused on healthy populations, but there is some evidence to suggest the findings may be different in clinical populations. Whilst females consistently give lower ratings of well-being in the general population in industrialized countries, this may not be the case when symptoms of anxiety and/or depression are present. Gender differences are apparent in adolescents without symptoms of anxiety and depression, whilst in those who do experience such symptoms, this gender difference is not evident. It is thought that gender may be a moderator in the well-being of adolescents with these symptoms, with males being more negatively impacted than females. Furthermore, it appears that males continue to experience lower SWB even after remission of symptoms. This may be due to gender differences in coping strategies, as well as the greater social sensitivity and emotional regulation demonstrated by females.

General Personality Factor

Juan-Carlos Pérez-González

Universidad Nacional de Educación a Distancia (UNED), Madrid

General Factor of Personality

Conceptualization and Relevance

The general factor of personality (GFP) is allegedly the most general personality dimension, accounting for very substantial amounts of the variance shared by high-order factors of personality, occupying the apex of the hierarchical structure of personality. A GFP can be located in most accepted measures of personality, be they normal or abnormal, and for the Five Factor Model (Big Five), which finding has been replicated a number of times across inventories and countries.

In short, the GFP (also Big One or B1) is considered a basic and adaptive biological disposition of non-cognitive personality, with an important genetic and evolutionary foundation. It integrates the variance that is shared by the positive pole of the broader factors of affection, motivation, temperament and personality.

The rediscovery of the GFP (i.e. Musek, 2007) is contextualized by the fact that the Big Five personality traits (B5), each of which was in theory independent or orthogonal to one another, have instead been found to be empirically interrelated. This justified the need to carry out more targeted factor analyses in order to explore or confirm the existence of super-factors of a higher order than the B5. As a result, two more general factors (Big Two or B2) were identified and situated above the B5 factors (e.g. DeYoung, Peterson, & Higgins, 2002), labeled Alpha or Stability (shared variance of agreeableness, conscientiousness and emotional stability) and Beta or Plasticity (shared variance of extraversion and openness). Later, Musek (2007) replicated the B2 solution and also found robust evidence of the GFP or B1 above the B2.

High scores for the GFP correspond to what could be considered a set of positive qualities of personality or an "ideal" personality (relatively high openness, conscientiousness, extraversion and agreeableness, and low neuroticism), which is best suited to a healthy adaptation to the collective life that is characteristic of our modern society. Thus, the GFP has been interpreted as the adult development of "good" temperament. Conversely, low GFP

scores correspond to what could be considered a "difficult" personality. Therefore, the GFP clearly has a positive and a negative pole. Those who approximate to the positive pole of the GFP are altruistic, pleasant, co-operative, relaxed, responsible, sociable and open people, who are mentally strong with a high self-esteem, and a subjective and psychological sense of well-being. People with a high GFP are socially and emotionally strong, which promotes interpersonal relationships, personal growth, and mental stability. Those who can be considered to lie at the negative pole of the GFP (lower scores) are those with an opposite profile in terms of such traits, corresponding to socially and emotionally compromised personalities, who have social problems and difficulties in coping with adversity, and in maintaining a state of well-being. Thus, it is these individuals who are more prone to suffer from psychopathological or personality disorders.

The most comprehensive reviews that present favorable (Irwing, 2013; Rushton & Irwing, 2011) and unfavorable (Ferguson, Chamorro-Premuzic, Pickering, & Weiss, 2011) perspectives on the GFP are included under the heading "References."

Life History Theory

It was Darwin who suggested that natural selection had endowed humanity with more co-operative and less controversial personalities. From this basic idea, the Life History (LH) theory was spawned, which J. Philippe Rushton adapted from the sphere of sociobiology to that of personality and that was further expanded on by José Aurelio Figueredo, who postulated that a combination of genetic traits are synergistically organized in humans to help them face the challenges of life (survival, growth and reproduction). This hypothetical combination of traits is a highly inheritable overarching dimension called "Super-K," which is presumably composed of three lower-order factors (that are also inheritable): a GFP; a "co-vitality" health factor that integrates various indicators of the overall degree of positive affect and well-being, such as physical and mental health; and a K-factor that brings together a diverse range of features related to personal, family, and social functioning, such as persistence, flexible re-evaluation, planning, and the quality of family and social relationships. According to this theory, the GFP is one of the main indicators of a global adaptive life strategy, consistent with a "slower" leaning in terms of mating and caring for offspring. Although this "slow" strategy is characteristic of humans and other animals (e.g. elephants), individual differences can also be appreciated within the human species. The "slow" or "K-strategy" involves devoting more resources to parental effort (having fewer children and taking good care of the offspring) and to a nepotistic effort (aimed at protecting the survival of the family) rather than a mating effort (focused on finding and maintaining sexual partners). By contrast, the "fast" or "r-strategy" characterizes those species or individuals who devote more resources to mating effort rather than parental or nepotistic effort, having more offspring but devoting less attention to them in order to better focus on ensuring their own survival. Accordingly, the GFP has been strongly associated with indicators of the "slow" life strategy.

Cross-Validation

The GFP has been located in a plethora of separate or combined inventories of personality or psychopathology (using both self-ratings and peer/others ratings) mainly through exploratory factor analysis (EFA) or confirmatory factor analysis (CFA) of existing or published

matrices (e.g. in test manuals or peer-reviewed journal papers), EFA or CFA of new data, CFA of meta-analytically derived correlation matrices, EFA of twin data, and CFA of multi-trait-multi-method (MTMM) twin data.

Following is a list of the main questionnaires from which the GFP has been extracted: EAS Temperament Survey for Children; Guildford-Zimmerman Temperament Survey (GZTS); California Psychological Inventory; Temperament and Character Inventory (TCI); Comrey Personality Scales (CPS); Multidimensional Personality Questionnaire (MPQ); Minnesota Multiphasic Personality Inventory-2 (MMPI-2); Millon Clinical Multiaxial Inventory (MCMI-III); Personality Assessment Inventory (PAI); Dimensional Assessment of Personality Pathology-Basic Questionnaire (DAPP-BQ); Multicultural Personality Questionnaire (MPQ); The HEXACO Personality Inventory (HEXACO-60); International Personality Item Pool (IPIP-300); Big Five Inventory (BFI); Big Five Observer (BFO); Gough Adjective Checklist; Occupational Personality Questionnaire (OPQ32); Hogan Personality Inventory (HPI); Trait Emotional Intelligence Questionnaire (TEIQue); The NEO-PI-R.

Biological Roots

The temperamental basis of GFP has been based on the Reinforcement Sensitivity Theory, especially on both the behavioral activation system (BAS) and the behavioral inhibition system (BIS). The GFP has been significantly positively correlated with the BAS and negatively correlated with the BIS. DeYoung et al. (2002) provided a possible neurobiological substrate for the B2 that has been also applied to the GFP. They suggested that Stability reflects individual differences in the functioning of the serotonergic system, which regulates the stability of emotion and behavior, while Plasticity reflects individual differences in the functioning of the dopaminergic system, which governs exploratory behavior (BAS) and cognitive flexibility. According to this hypothesis, it is expected that individual differences in serotonergic and dopaminergic function might be at least partially responsible for the pattern of intercorrelations among the B5. Therefore, a high GFP can be expected to be also associated to higher balanced levels of serotonin and dopamine.

Regarding the evolutionary genetics base of the GFP several cross-national twin studies have found that 50% of the GFP variance is due to genetic influence and 50% to non-shared environmental influence (e.g. due to any personal experience such as an illness or chance friendship that happens to one sibling and not to the other), similar to that found for the B5. Likewise, some relevant part of the genetic variance in the GFP is allegedly of non-addiditive variety (dominance and epistasis). All these results support the idea that the GFP is largely a genetic factor.

Critical Questions for Construct Validity: Existence, Consistency, and Psychological Meaning

The main criticisms of the GFP focus principally on three issues: its very existence, its consistency, and its psychological meaning. As for the existence of the GFP, although it is beyond dispute that the B5 factors are interrelated and that more general super-factors can be obtained through factor analysis, the critical question is whether these factorial solutions (both B2 and GFP) are substantive or artifacts. Since the GFP has been replicated in

numerous studies, one could conclude that it obviously exists. However, some critics have suggested that the procedures used to extract the GFP in the factor analysis are inappropriate, which may introduce a bias into the results. In addition, its critics point out that the correlations between the B5 factors are not as high as those between cognitive abilities, indicating that the psychometric and theoretical relevance of a GFP is not at all comparable with that of the general factor of intelligence. Indeed, meta-analyses have shown that a univariate hierarchical model of personality (B5-B2-B1) may have a weaker relevance than a bifactor model (B5-B2-B5-B1) in which the B5 simultaneously share their variances with B2 as the pair of higher-order factors, and with GFP as the single higher-order factor.

Concerning the consistency of the GFP, a number of studies have found that GFPs extracted from different personality inventories have considerable overlap, with an average correlation of about r = .60. This fact indicates that the GFP is invariant across instruments and samples. However, it has been found through meta-analysis that the GFP is reduced substantially when based on between-inventory data (26%) compared to within-inventory data (50%), which has been interpreted by critics as robust evidence that the GFP is at least partially an artifact response that may be reduced by administering scales from different inventories before conducting the extraction of the latent variable.

The possibility that the GFP may be just a statistical artifact of the unification of the variances since the responses to personality questionnaires may be biased toward a socially desirable rating is one of the main criticisms of the significance of the GFP. However, although the GFP does include part of this variance, it is not simply reduced to it. Numerous studies, and even some meta-analyses, have shown that social desirability does not cancel the substantive component of the GFP. For example, it has been confirmed that the GFP is a better indicator of social effectiveness than of social desirability. Accordingly, individuals with a high GFP are indeed more prone to co-operation, yet experimental research using The Prisoner's Dilemma has also shown that this inclination is not inflexible, such that people with a high GFP may stop co-operating if the co-operating of the other party so demands.

The GFP represents, to some extent, an intelligent personality, that is to say a collection of positive and generally adaptive personality traits. Regarding its psychological meaning, the GFP symbolizes a predisposition to be emotional and socially efficient. In this sense, since the GFP reflects a mix of socially desirable dispositions, the GFP has been presented as reflecting social effectiveness. Consistently, advocates of the GFP have argued that the high end of the GFP is emotional intelligence (e.g. Rushton & Irwing, 2011). In fact, the highest correlations between the GFP and other constructs are precisely those of the GFP with social effectiveness and trait emotional intelligence (somewhere around r = .65–85).

Critics have highlighted that the next wave of studies have to show that the GFP could predict (criterion validity) theoretically relevant real-life outcomes (e.g. academic performance, job performance), especially over and above (incremental validity) other non-cognitive global predictors such as the B5, the B2, or trait emotional intelligence. This is particularly necessary using objective (non-self-report) measures of the criterion variables.

As for its divergent validity, there appears to be a positive association between the GFP and *g*, although its association with specific cognitive abilities and other variables at the personality-intellect interface is less clear, like creativity (e.g. divergent thinking). However, it is expected that the magnitude of these correlations would be low, despite being positive and significant.

Genetic Basis of Personality

Claire A. Wilson

University of Western Ontario

Behavioral Genetics

The field of behavioral genetics consists of interdisciplinary research that studies variations in human behavior to determine the extent to which individual differences in behavior are attributed to genetic or environmental factors. Early research in behavioral genetics focused on determining the heritability of various traits and behaviors. Heritability is defined as the proportion of observable behavioral variance that is due to genetic variation. That is, heritability is the extent to which individual differences in behavior are due to genetic differences between individuals. These genetic differences can be broken down into additive and non-additive effects. Additive effects are genes that contribute linearly, regardless of what other genes are present, while non-additive effects are dominant genes that contribute in a non-linear fashion. The remaining sources of variance are shared and non-shared environmental variance. The shared environment is any aspect that twins or siblings both experienced, such as parenting styles and socio-economic status in childhood. Non-shared environmental factors are occurrences that one twin or sibling experiences but the other does not. Different friend groups, teachers, or traumatic accidents are considered examples of non-shared environmental effects.

Methods

The two most common methods of measuring heritability are twin studies and adoption studies. Twin studies involve collecting data from sets of both monozygotic (MZ; identical) and dizygotic (DZ; fraternal) twins. MZ twins are born from the same embryo and have the exact same genetic makeup. DZ twins are born from two different embryos and share approximately 50% of their genes. The logic behind twin studies is simple: if MZ twins are more similar on various traits than DZ twins, than these traits are considered to be influenced by genetic factors to some degree. The basic formula for calculating rough estimates

of heritability involves correlations, such that heritability equals two times the difference of the correlation between MZ twins and the correlation between DZ twins. As a formula it is written as $h^2 = 2(r_{MZ} - r_{DZ})$. More recent behavior genetic studies use a more complex model-fitting approach to estimate genetic and environmental effects (for more information see Further Readings).

One criticism of twin studies is that it assumes that both MZ and DZ twins experience the same degree of shared environmental similarity. This assumption has been criticized because it is believed that MZ twins may be treated more similarly than DZ twins, and therefore, the greater correlations between MZ twins could be attributed to the greater environmental similarity that they experience compared to DZ twins. While the equal environments assumption remains a criticism in the area of behavioral genetics, there is little evidence to suggest that it is a major confounding issue in twin studies. Furthermore, direct tests of this assumption demonstrate that even if MZ twins are treated more similarly, this is not a contributing factor to the larger correlations found between MZ twins.

Another method used in behavioral genetic research is adoption studies. Adoption studies are a valuable tool to help disentangle the genetic and environmental influences in genetically similar families. Adoption studies may take two forms. The first looks at family members who are genetically unrelated and living together; this method is able to determine the extent to which shared environmental influences are present among family members. The second is concerned with family members who are genetically related but are living apart; this method allows for the testing of genetic influences. Another useful approach in this field is family studies. This method assesses heritability using a broader family scope including parents, siblings, grandparents, cousins, and so forth. In each of these methods, the goal is to determine the extent to which individual differences are due to genetic and/or environmental differences – either shared or non-shared. The earliest twin and adoption studies focused on general cognitive ability (*g*), otherwise known as general intelligence, which is assessed by intelligence quotient (IQ) tests. Average correlations for MZ and DZ twins are .86 and .60 respectively, .47 for non-twin siblings, and .32 for adopted siblings. General intelligence is highly heritable with 50% of the variance due to genetic influence, 25% due to non-shared environmental effects, and 25% due to shared environmental effects.

The Heritability of Personality

It is now well accepted in personality research that approximately 30–50% of the variance in personality traits is a result of additive genetic influence, with the remaining variation coming from non-shared environmental effects. Non-additive genetic effects and shared environmental effects contribute negligibly to the variation of individual personality traits. The Big Five personality traits (extraversion, agreeableness, neuroticism, conscientiousness, and openness to experience) have been studied extensively in the area of behavioral genetics. An abundance of data has been collected from MZ twins and DZ twins raised both together and apart, and a variety of other sibling relationships such as non-twin biological and adopted siblings. The heritability estimates for each of the five traits are substantial, ranging from 43% to 54%. Studies have found relationships between the Big Five and other constructs such as depression, humor styles, and entrepreneurial tendencies, all of which demonstrate a certain level of heritability.

In addition to classical personality models (e.g. the Big Five), behavioral genetic research has examined other individual differences in personality, such as attitudes, empathy, parental attachment, and self-esteem. For instance, traditionalism is the extent to which an individual has liberal or conservative views on a variety of matters. Initially, this attitudinal dimension was not expected to demonstrate any significant genetic influence, however, heritability estimates of approximately 50% have been found. Researchers looking at individual differences in political attitudes are interested in which political party individuals identify with and how intensely they identify with this party. Political party identification consists of mainly shared environmental influence, whereas the intensity with which individuals identify with a party is a result of genetic and non-shared environmental influence.

Twin studies have also assessed heritability estimates of empathy across age groups. Evidence suggests that empathic responses demonstrate increasing genetic influence from infancy through to adulthood. Furthermore, attachment research suggests there is genetic influence for children's perceptions of parental warmth, but no genetic influence for children's perceptions of parental control. Attachment styles demonstrate modest heritability estimates, but considerably more shared environmental influence. Lastly, there is modest genetic and substantial non-shared environmental influence on individual differences in self-esteem, but no evidence of shared environmental influence.

Another aspect of personality that has been an area of focus in behavioral genetic research is personality disorders. Personality disorders are a rigid and stable cluster of maladaptive personality traits. These traits are seen as a normal part of personality by the person with the disorder, but are often a cause of significant distress to those around them. Few studies have collectively compared all of the heritabilities of existing personality disorders. However, a study of Norwegian adult twins assessed the heritabilities of all personality disorders recognized by the American Psychiatric Association, except for antisocial personality disorder. They found that heritability estimates ranged from 28% (paranoid and avoidant personality disorders) to 79% (narcissistic personality disorder), with an overall heritability estimate for personality disorders of 60%. While not included in the Norwegian study because of low occurrence in the selected sample, antisocial personality disorder has been studied extensively in behavior genetic research. Heritabilities for antisocial personality disorder range from 50% to 60%.

Other Applications of Behavior Genetics

While much of the early research has provided insight into the heritabilities of various personality traits, recent work has focused on studying the relationship between genetic and environmental factors. This interplay between genes and environment is evident in two ways: gene–environment correlations and gene–environment interactions. Gene–environment correlations refer to experiences being more likely to happen to people with certain genetic predispositions. For instance, men who experience greater social potency and achievement, and women who experience greater social closeness and harm avoidance, are more likely to get married than individuals who score low on these personality traits. Gene–environment interactions refer to the environment being affected by our genes or our genes being affected by our environment. For example, children who have a genetic

propensity for aggression have a greater risk of behaving aggressively but only when they have a poor relationship with their teacher.

Longitudinal twin studies are an effective means of determining the stability of genetic and environmental influences on personality over time. It allows researchers to address a number of questions such as: does heritability change or remain stable over time? Research shows that the contribution of genetic influences (i.e. heritability) decreases slightly over an adult's lifespan. The greatest contribution is seen in early adulthood, and then it slowly decreases into middle and older age. On the other hand, the contribution of environmental influences becomes more prominent over the life-span. Another question that can be explored through longitudinal twin studies is whether or not genetic and environmental differences in individual personalities remain stable or change across adulthood. Research suggests that from mid-adulthood and onward, genetic influences on differences in personality remain quite stable over time. Conversely, environmental influences on individual personality differences are not very stable in early adulthood, but become increasingly stable from middle adulthood and onward.

Molecular Genetics

Molecular genetics, a field closely related to behavioral genetics, combines the areas of biology and genetics to examine both individual genes and groups of genes at the molecular level. By examining the molecular makeup of genes, scientists are able to pinpoint which genes are responsible for certain diseases. However, in personality research, it is much more difficult to map genes to specific traits. Unlike molecular genetic research in other fields where a single gene may be responsible for a particular disease or disorder (e.g. cystic fibrosis and Huntington's disease), personality traits are not established from one gene. Instead, personality traits are linked to multiple genes that all contribute slightly to the trait, incidentally making them much more difficult to identify. While mapping genes to personality would transform both genetic and personality research by allowing for much more precise analyses, it is an incredibly daunting task. However, despite the incredible difficulties associated with molecular genetic research in personality, there have been a number of traits that have been linked to certain genes. Novelty seeking and neuroticism have been linked to dopamine and serotonin activity, respectively. Future technology will undoubtedly allow researchers to delve further into the world of molecular genetics and personality. New models must consider the interplay between genes and the environment in order to fully understand the genetic basis of personality.

Gene–Environment Interaction

Breanna E. Atkinson and Philip A. Vernon

University of Western Ontario

Behavioral genetics as applied to humans refers to the scientific study of the nature and origin of individual differences or of variations between people. Some behavioral geneticists also work with non-human animals. Fundamentally, individual differences can be attributed to genetic differences and to differences in the environment. Genetic effects can be either additive or non-additive (see twin studies of personality), while environmental effects are either shared or non-shared. However, only non-shared environmental effects can contribute to individual differences.

Two additional sources of variation are genotype-environment correlations and genotype-environment interactions. $G \times E$ interactions are the topic of this entry but in order to distinguish between these and $G \times E$ correlations the latter will also be described.

A $G \times E$ interaction occurs either when the way in which a genotype expresses itself varies as a function of the environment or when the effects of an environment vary as a function of the genotype. To illustrate, consider that identical (or monozygotic, MZ) twins, who share 100% of their genes, have about a 48% concordance rate for schizophrenia, whereas fraternal (or dizygotic, DZ) twins, who share about 50% of their genes on average, only have a 17% concordance rate for schizophrenia. The difference between the MZ and DZ concordance rates clearly indicates a genetic contribution to the development of schizophrenia but the fact that the MZ rate is less than 50% also means that in discordant pairs the twins must have been differentially exposed to one or more environmental triggers. This, in turn, illustrates that the genetic predisposition to schizophrenia manifests, in part, as a function of the environment, which defines a $G \times E$ interaction.

There are several ways to investigate $G \times E$ interaction, including animal studies, family studies, studies of adoptees and their adoptive and biological parents, twin studies, and molecular genetic studies.

Animal studies are typically conducted in a laboratory and have the advantage that the environment can be directly manipulated and that animals can be randomly assigned to different environments. The animals' genotypes can also be manipulated. Consider the well-known study by Cooper and Zubek (1958) in which rats were bred to be either adept

or poor at running mazes ("maze bright" and "maze dull"). Members of the two breeds were then assigned to be reared either in an enhanced environment, in which they had colored cages and toys, or in a restricted environment, which was not colored and which had no toys. Being raised in an enhanced environment greatly improved the maze-running ability of maze dull rats while having no effect on the ability of maze bright rats. Being raised in a restricted environment, conversely, had no effect on the maze dull rats but greatly diminished the maze-running ability of the maze bright rats.

Family studies focus on similarities and differences between parents and their biological offspring and between biological siblings raised together. They do not include adoptive children or twins and, as such, cannot tease apart the separate effects of genes and the environment. They can, however, be informative with respect to G×E interactions. To illustrate, Cannon, Mednick, and Parnas (1990) compared high versus low functioning children of schizophrenic mothers and identified a number of salient differences between the groups' environments. Despite both groups being equally genetically at risk for schizophrenia, the low functioning children, who had presented with some form of psychiatric disorder, were more likely to have been exposed to prenatal and birth complications and to have been separated from their mothers early in development due to their mother being hospitalized.

Adoption studies can illustrate G×E interactions as long as information is available concerning the adoptees themselves and both their adoptive and biological parents. Relations between adoptees and their adoptive parents are attributable to their shared environment whereas similarities between adoptees and their biological parents are due to their shared genetic material. A G×E interaction may occur if the adopted children's genetic predisposition toward some behavior is enhanced or diminished as a function of their adoptive home environment. In two studies, for example, adopted children whose adoptive parents had a criminal record were more likely to be convicted of crimes themselves if their biological parents also had a criminal record (Bohman, 1996; Brennan, Mednick, & Jacobsen, 1996).

Twin studies are used in a variety of ways to investigate G×E interactions. In a number of twin studies, for example, it has been demonstrated that the genetic contribution to individual differences in traits and behaviors varies as a function of the environment. The heritability of alcohol abuse, for example, is higher in more permissive rearing environments, and the heritability of general intelligence, estimated using twins, is substantially larger among families in which the parents are more highly educated (Plomin, DeFries, McClearn, & McGuffin, 2008). Studies of identical twins separated at birth and raised apart in different environments are another powerful way to detect G×E interactions.

Molecular genetic research seeks to identify specific genes which contribute to traits and behaviors, and the extent to which the effect of a gene or genes on individuals varies as a function of environmental circumstance. One gene (MAOA), for example, has been associated with antisocial behavior among individuals exposed to maltreatment during development, while showing no such significant association among individuals who had not been abused. Another gene (5-HTT) has been associated with depression among individuals who experienced stressful life events but was found not to be associated with depression among individuals who reported little stress in their lives. A number of other molecular genetic studies have also reported various G×E interaction effects (see Plomin et al., 2008).

Two more recent approaches to studying G×E interactions include polygenic investigations, in which the effect an environmental factor may have on multiple genes is identified,

and focusing on three-way gene x environment x environment interactions, which show the interactive effect that multiple environmental factors may have on a genotype.

It is useful to distinguish between G×E *interactions* and gene–environment *correlations* because they are at times confused or used interchangeably, in the popular press if not in scientific circles. As described, G×E interactions occur when the way in which a genotype expresses itself varies as a function of the environment or when the effects of the environment vary as a function of the genotype. Gene–environment correlations, in contrast, refer to ways in which an individual's environment may be shaped, in part, by their genetic predispositions.

Plomin et al. (2008) describe three types of gene–environment correlation – passive, evocative, and active – and illustrate each of these with the example of musical talent. Assuming musical ability is heritable then a child with musical talent is likely to have at least one parent who is also musically inclined. The child has thus received a genetic predisposition toward being musical and it is also likely that their parents expose them to music at home or by going to concerts or providing them with music lessons. These instances are examples of a passive gene–environment correlation: the child has passively inherited both genes and an environment which contribute to their development of a talent for music. An example of an evocative gene–environment correlation might be a teacher who recognizes a child's potential for music and who encourages the child to join the school band or who provides the child with other opportunities to help them realize their potential. Finally, a musically gifted child may be driven to seek out such opportunities for themselves: an example of an active gene–environment correlation. Gene–environment correlations can be investigated through comparisons of adoptive and non-adoptive families. They can also be detected in adoption studies by examining the correlation between the scores of the adopted child's biological parents on a given trait or behavior and the child's adoptive rearing environment. Finally, gene–environment correlations can be illustrated through multivariate behavioral genetic studies which examine the extent to which the genetic effects on a measure of the environment correlate with genetic effects on measures of a trait or behavior.

In conclusion, G×E interactions are another contributor to individual differences. The importance of G×E interactions has become increasingly recognized over approximately the past two decades. G×E interactions can be identified through a number of different behavior genetic designs and by studying humans and non-human animals.

Genius, Personality Correlates of

Gillian C. Tohver and Chloe Lau

University of Western Ontario

What is Genius?

The complexity of the genius construct has created difficulties for a scientifically precise and inclusive definition (e.g. Treffert, 2010). Common descriptors of genius include "intellectual," "creative," "mad," "hardworking," and "misunderstood," yet these characteristics at best represent correlates or symptoms of genius. However, researchers typically define genius as the general co-occurrence of creativity (i.e. the multifaceted ability to formulate new ideas based on existing ideas), achieved eminence, and superlative intellectual ability (i.e. exceptionally high logical, analytical, and mechanical reasoning, alongside creative problem-solving abilities). There are many ways to achieve eminence, such that geniuses are heterogeneous (Simonton, 2012). Specifically, achieved eminence can be the creation of at least one exceptional domain-specific product that is original (i.e. creative) and acknowledged as adding considerable value to the discipline. It is important to recognize that the genius label is somewhat subjective and socially dictated, as individuals' venerable contributions only matter for the labeling of genius if others recognize and value the contributions. Also, the degree of creativity involved depends on the state of the discipline (i.e. a well-developed discipline requires more creative thought to be original). Therefore, genius depends on the time and culture in which the genius individual (1) lived and (2) is being judged from (many geniuses are only recognized posthumously).

Intelligence and Genius

While general intellectual ability is necessary for creative genius as defined by scientists, it alone is not sufficient for qualifying the label. Many individuals with exceptionally high intelligence scores have not produced innovative or exceptional contributions.

Geniuses generally represent the upper tail of the highly skewed intellectual ability distribution, with scientifically-inclined and artistically inclined geniuses (i.e. those who have

a greater focus on the sciences or the arts) typically possessing IQ scores between 140–155 and 125–130, respectively. However, genius' exceptional creative achievement is robustly linked to intelligence, such that intelligence may be necessary for outstanding creative potential and divergent thinking. Meta-analytic findings likewise show intelligence is moderately positively correlated with divergent thinking (Sánchez-Ruiz et al., 2011).

Origins of Genius

Genius is the product of additive and multiplicative effects of disposition (genetics, personality) and environment (sociocultural pressures) interacting. Genes heavily predispose individuals toward genius, wiring faster learning/improvement, high intellectual/cognitive abilities, and general personality trait patterns to further foster creativity and achievement. Specifically, meta-analytic research shows that 20% of the variation in creative achievement is due to genetics (Simonton, 2015)

However, nurturance factors are also necessary, as brilliance requires encouragement and an educational knowledge base to build from. Specifically, the genius' creative component operates after mastering one or more disciplines (e.g. the 10-year expert theory). Creative thought processes are also posited as being sensitive to and changed by the environment (i.e. geniuses form deep, inspirational connections with their social and physical environments). Historical accounts show oscillations over time for creative genius, suggesting that situational factors (e.g. culture) influence genius expression. Also, creativity is understood and expressed differently cross-culturally. For example, Western cultures judge creative endeavors far more in terms of useable products while Eastern cultures judge them based on personal fulfillment/enlightenment products, and individualistic cultures often foster more creative expression than collectivist cultures (Glăveanu, 2010). Hence, culture influences the occurrence of and subjective value society ascribes to geniuses' creative endeavors.

Measuring Genius

Numerous methodological approaches are used to identify unifying features of creative genius, from non-generalizable psychobiographic case studies that predict personality via historical document to quantitative comparison of extant genius and non-genius samples to multi-case personality profile comparisons of geniuses from different domains (e.g. artistically vs. scientifically inclined geniuses). Unfortunately, aggregate statistical paradigms risk losing crucial ideographic information about the development of genius and all methods for studying genius are retrospective, occurring only after genius has been publicly recognized and labeled. Also, genius is not strictly the dichotomy that researchers and society conceptualize it to be, as individuals differ in the magnitude of their exceptional achievement, intelligence, and discipline contributions. To overcome these issues, future consideration of genius needs to explore it along a more precise, continuous spectrum to better understand the construct. As well, non-profit "genius organizations" (e.g. Mensa International, the Four Sigma Society, the Prometheus Society, etc.) offer many potentially

invaluable genius-generated tests, varying widely in their content, admission stringency (i.e. from 1 in 50 to 1 in 11,000), and metric validity, that scientists should also utilize to better understand genius and its personality indicators as identified by highly intelligent potential geniuses and recognized geniuses.

Personality Correlates of Genius

Beyond genius' informal correlation to personality through historical case studies, the connection between genius and personality has been highly contested, with some theorists subscribing to the cognitive view that no qualitative personality differences exist between geniuses and non-geniuses (only knowledge base and practice factors). Others proposing the psychometric view that creative genius, founded on sensitivity to problems and divergent thinking, may itself be part of personality, making a particular personality profile a prerequisite of the genius label. This personality perspective is controversial as personality–genius relations have not yet been shown to be causal in nature (Weisberg, 2010). Furthermore, because labeled geniuses are not a homogeneous group, personality profile differences exist within the group.

It should also be noted that personality and individual difference traits' outcomes – their utility and adaptive value – change within geniuses compared to the general population. For example, high intelligence appears to significantly moderate psychopathologic tendencies and traits that are negative in the general population such that they can be less harmful or positive for geniuses (Simonton, 2012). Conversely, creativity, which enhances mental health in the general population, inhibits geniuses' overall mental health (Simonton, 2014). Despite these interpretive complexities, some personality tendencies are common in geniuses. The classic creative personality of many geniuses includes high autonomy/non-conformity and tolerance for ambiguity.

In terms of major personality traits, geniuses historically display low levels of agreeableness (the tendency to be interpersonally acceptable and co-operative) and impulse control, though scientifically inclined geniuses show higher agreeableness than artistically focused geniuses. Scientifically inclined individuals also show higher conscientiousness (the tendency toward order, dutifulness, and diligence) than artistically inclined individuals.

Openness (the tendency to willingly try or be exposed to new experiences) is also high in geniuses, particularly those very high in creativity. In fact, cross-culturally, the openness construct overlaps with traditional intelligence (DeYoung et al., 2012). This elevated openness is credited with forming geniuses' extreme behavioral versatility and desire to have an unusually wide array of interests and hobbies (e.g. the most distinguished scientists have strong artistic abilities/avocations compared to less distinguished colleagues, and lauded artists demonstrate avid scientific interests). Likewise, imaginativeness (a facet of openness) partially explains variation in individuals' divergent thinking and the *blind variation and selective retention* (BVSR) theory of creativity requires openness, positing that creativity emerges through being open to trying new, fallible ideas. Multicultural exposure, which indicates and enhances openness, is also highly associated with genius creativity.

Extraversion is also often positively correlated with overall creativity and genius, but meta-analytic research has since shown that the relation is driven solely by a single extraversion

facet, high self-confidence (often interpreted as arrogance or, erroneously, hostility), rather than extraversion overall (Sánchez-Ruiz et al., 2011). In fact, counter to extraversion's primary facet, sociability, geniuses are typically asocial (i.e. low interest in being social, but not hostile/antagonistic toward others) or withdrawn/internally preoccupied, with many geniuses having neither spouses nor children. Like hostility, however, extreme self-confidence can make genius' agreeableness shift. The self-confidence facet is particularly high in scientifically inclined individuals. However, "revolutionary/controversial" (i.e. rule-challenging) and scientifically inclined geniuses can also sometimes display other facets of extraversion (high risk-taking and competitiveness).

More negatively, high neuroticism is also typical in geniuses, especially for artistically inclined and controversial geniuses. While variation in divergent thought is partly explained by neuroticism-based histrionic and skeptical (paranoid) tendencies, very high neuroticism can also impede creative potential via over-fixation blocking problem-solving. Hostility (a facet of neuroticism rather than extraversion) can also make genius' agreeableness fluctuate. Similarly, psychoticism (i.e. hard-mindedness, not "madness") is also generally high in geniuses, particularly artistically inclined or controversial ones. Likewise, divergent (creative) thinkers are at a somewhat higher risk for developing some addictions and psychopathologies (e.g. depression, suicidality, psychosis, mania, anxiety), though this risk appears to be caused primarily by having high neuroticism rather than being true of all geniuses. For example, scientifically inclined geniuses, who possess higher emotional stability (i.e. lower neuroticism) than artistically inclined geniuses, are at less risk.

Researchers have also recently observed mediational relations between some geniuses (e.g. controversial geniuses) and increased dishonesty via a lack of concern over rules and the desire to creatively problem-solve in order to challenge rules (Gino & Wiltermuth, 2014).

Genius and Motivation

While explicit personality relations to genius are substantial (if complex), it is important to emphasize one critical, personality-related correlate of genius: motivation (or, perseverance, tenacity, or "grit"). For geniuses to act on and achieve their potential, it is crucial they be intrinsically motivated, with the strength to fail and back-track repeatedly (e.g. the BVSR creativity theory). Conversely, extrinsic motivation impairs genius' productivity and achievement.

Practical Implications

Though dispositional genius factors are predominantly beyond our control (possibly excluding exceptions fostering openness via exposure to novel experiences and therapeutically treating neuroticism), policy makers and citizens can optimize genius in society by promoting environmental factors such as education, emphasizing (1) acquiring a broad knowledge foundation spanning disciplines and (2) training children and adults to

actively transfer knowledge across domains. Institutions should also promote a culture of ethics-driven experimentation, accepting failure as an integral part of learning, over the current blame and threat-avoidance cultures that discourage citizens from entrepreneurial endeavors for fear of being personally challenged or failing.

Guilt

Kristi Chin

University of Michigan

Introduction: What Is Guilt?

There are three fundamental features of guilt. First, guilt is self-conscious and involves self-evaluation. Second, guilt involves morals and can influence us in intrapersonal (i.e. who we are) and interpersonal (i.e. our relationships with others) ways. And last, guilt is negatively valenced and typically causes us to experience negative emotions. However, some experiences of guilt are beneficial: people who are prone to feeling guilty are better able to empathize with others and accept responsibility for negative interpersonal events more readily. There are two ways to conceptualize guilt based on how negative emotions are experienced: anxious guilt is experienced when people fear punishment as a result of doing wrong, and empathic guilt is experienced when one feels that they have done wrong to others.

Guilt can also be categorized based on theoretical origins. In Freud's psychodynamic approach, guilt has been related to the Oedipal stage of psychosexual development. Guilt was seen as occurring in the unconscious where it worked as a catalyst for defense mechanisms aimed at shielding people from experiencing the guilt produced by their inner desires. In addition to Freud's psychodynamic approach, guilt has also been linked to the Initiative versus Guilt stage of Erik Erikson's psychosocial development theory. At this stage, between the ages of 3 to 5 years, play is central and initiative is encouraged. Children who were not encouraged to express themselves freely were thought to develop guilt, which later was thought to manifest into a fearfulness of initiative in adulthood.

Guilt has also been studied from a more cognitive approach. According to this perspective, guilt is believed to occur because people feel as though they have caused harm, and these thoughts yield negative emotions. Additionally, the experience of guilt may occur as the result of feeling responsible for another's real or imagined misfortune. When people go to therapy to address their feelings of guilt, therapists typically help guide clients to become aware of and eliminate negative, dysfunctional, and automatic attitudes. This allows clients to notice when

they experience catastrophizing processes (making the worst of a bad situation) and when they overgeneralize (if one bad thing happens, more bad things can happen too).

There are four general types of interpersonal guilt: survivor guilt, separation guilt, omnipotent responsibility guilt, and self-hate. First, people may feel bad for their own good fortune because others do not experience the same fortune. This is a phenomenon known as survivor guilt. For example, someone who wins the lottery may feel guilty that others who need money do not share their stroke of luck. As a result, people who experience survivor guilt may begin self-destructive behaviors to limit their success and mitigate their guilty feelings. Next, separation guilt is described as the experience when one feels guilty for being distant or different from those who are important to them. For example, people who are physically distant from their parents or who have very different interests from their parents may experience separation guilt. The third type of interpersonal guilt is omnipotent responsibility guilt, which originates from altruism (i.e., the selfless concern for the well-being of others). Omnipotent responsibility guilt is experienced when people feel that they have a role in the success and happiness of others but have failed to meet this role. People who experience this omnipotent responsibility guilt may engage in helping behaviors toward others to alleviate their distress. The first three types of guilt discussed are other-focused, because they are based on empathy and incorporate the feelings and behaviors of others, whereas self-hate is self-focused and indirectly based on empathy. This final type of guilt is produced when people accept critical evaluation of themselves from others. Self-hate guilt is associated with negative emotions and is classified as a maladaptive form of guilt because the experience of self-hate guilt has little social benefit.

Across the Lifespan

Although the nature and strength of guilt change with development, individual differences in guilt are stable from middle childhood to early adulthood. Parenting styles are a large factor in how moral emotions develop and how likely we are to feel guilty. Researchers who study the development of guilt in toddlers measure discomfort after transgressing as a representation of guilt. Toddlers who were more likely to show greater discomfort after transgressing were also likely to respond with more fear toward risky activities. In addition to risky activities, children are highly perceptive to how their parents react and respond to the errors that children make. For instance, sons develop greater guilt when they have fathers who react particularly negatively to their errors. Although there is a strong association between feelings of guilt and how fathers respond to errors made by their sons, in general, women report greater guilt than men across all age groups as a result of being more self-reflective, attuned to morality, and greater willingness to report on their emotional experiences. Men may, in fact, experience high guilt, but may not be as open to admitting to these feelings of guilt.

Guilt and the Five Factor Model

With regard to personality, guilt may differ depending on individual differences in the Five Factor Model. People who are higher in extraversion (who are typically social, fun-loving, and passionate) are less likely to experience anxious guilt and other forms of guilt that include worry of punishment. People higher in neuroticism (who are likely to worry and are described as nervous and vulnerable) are more likely to experience anxious guilt. Lastly,

more agreeable people (who are typically helpful, good-natured, and kind) are more likely to experience empathic guilt and tend to feel strong reparative urges because they prefer to get along with others.

Guilt and the Dark Triad

The Dark Triad is a personality model that comprises three sub-clinical personality traits: narcissism, Machiavellianism, and psychopathy. People higher in narcissism have excessive self-love and tend to feel superior compared to others. People higher in Machiavellianism are typically charming, manipulative, and lacking in morality. Lastly, people higher in psychopathy are impulsive and callous. More narcissistic people are less likely to experiences all four types of interpersonal guilt. People higher in Machiavellianism and psychopathy are less likely to experience omnipotent responsibility and do not appear to feel guilty when they fail to help others, but are more likely to experience self-hate guilt. That is, people higher in Machiavellianism and psychopathy tend to experience greater feelings of guilt caused by real or imagined evaluation from others.

Similarities to Shame

Shame is very similar to guilt and psychologists have used the terms interchangeably in research. Both shame and guilt share a number of features, including similar situations, facial expressions, and interpersonal emotions. Differences between shame and guilt may lie in the type of events that produce each emotion. Shame is experienced as a consequence of failure due to personal inadequacy whereas guilt is experienced as a consequence of failure that could have been controlled. We can also differentiate shame and guilt based on whether the nature of the event is public (shame) or private (guilt). We can further differentiate shame and guilt by whether the emotions are caused as a failure of the self or as a failure of behavior. People who experience shame evaluate their global self (i.e., the general value they place on themselves) and are concerned that others are also evaluating their global self. People who experience guilt evaluate their behavior, rather than the global self, and are concerned that others are evaluating their behavior as well. Shame arises from feelings of inadequacy and can be associated with more maladaptive patterns. Thus, shame typically includes a greater degree of distress than does guilt, resulting in feelings of shrinking, worthlessness, and powerlessness, and a desire to hide or strike back. In comparison, guilt arises from distress over violation of internal conscience. Thus, guilt includes a greater degree of tension, remorse, and regret, and a desire to confess, apologize, or repair.

Health and Personality

Gillian C. Tohver and Anita Feher

University of Western Ontario

Personality links to physical and mental health begin early in life and act as major contributors to long-term adjustment, coping, and wellness. Specifically, personality characteristics influence predisposition to adaptive and maladaptive coping strategies, and tendency toward clinical diagnoses. Research indicates that most personality traits simultaneously possess positive and negative influences on health. However, as personality's influence (i.e. its strength and nature) on diagnoses, well-being, and coping varies depending on the particular coping-inducing stressor(s) or traumas, the situation, or context, surrounding illness must be concurrently considered in explaining health outcomes.

Biopsychosocial Model

One model used to explain the influence of psychological factors on health is the biopsychosocial model. Originally proposed by Engel (1977), this model postulates that both psychological and social elements must be considered alongside biological factors when it comes to understanding health and illness in humans. This is a deviation from the biomedical model, which only considers biological factors. Using the biopsychosocial model, factors such as personality are considered one of the many influences that work together to impact health.

Type A, B, C, and D Personality

Type A and Type B personalities are individual difference profiles relating mainly to behavioral patterns. Type A individuals typically demonstrate increased aggression and hostility, a competitive drive, and time-related urgency (see Rosenman & Friedman, 1977). Type B personality is the lack of many of the characteristics related to Type A individuals, and is not associated with disease proneness. Belonging to the Type A group has been generally

associated with coronary heart disease-related complications. However, recently this dichotomy has been questioned, and new evidence suggests that instead of general Type A behavior patterns being harmful to health, it is specifically the hostility component that has harmful health consequences. A Type C "cancer-prone" personality was also developed to describe characteristics including negative emotional expression difficulties and excessive inhibition of emotions, though it is controversial and generally not supported in the literature. More recently, a new Type D (i.e. distressed) personality, characterized by social inhibition and an inclination for negative affectivity, has been linked to negative health consequences and increased mortality risk.

Neuroticism

Neuroticism is a personality factor characterized by emotional instability, anxiety, and negative affect. A review by Lahey (2009) shows that neuroticism is negatively associated with both physical and mental health complaints. Neuroticism has been positively related to health issues, including chronic pain experiences, asthma, greater mortality risk, mood disorders, anxiety disorders, alcoholism, reports of poor general health and quality of life, as well as increased likelihood of making unsupported health complaints. Reasons for this negative relationship between neuroticism and health can be explained by a multitude of factors, including higher physiological and emotional reactions to stress, less social support, inefficient coping strategies, increased focus on bodily states, poorer health management, as well as engaging in negative health behaviors.

Recent research however suggests the existence of "healthy neuroticism," originally proposed by Friedman, which is the combination of high neuroticism with high conscientiousness personality traits (see Turiano, Mroczek, Moynihan, & Chapman, 2013). Healthy neuroticism has been associated with beneficial health consequences, including decreased inflammation levels, and less smoking comparatively after disease diagnosis. One explanation is that increased health anxiety associated with neuroticism when paired with conscientiousness results in better health behaviors.

Extraversion/Introversion

Extraversion, the first factor in most personality frameworks, is defined as the behavioral tendency to be bold and energized by high external activity and frequent interaction with other individuals. Conversely, introversion (conceptualized by most as the opposite pole of the spectrum) is the tendency to be energized by internal thoughts and personal exploration. Jung's seminal construction of extraversion and introversion was as distinct, normal, and neutrally adaptive personality types. Specifically, the adaptiveness of extraversion/introversion for health in human and other animals is dictated by whether the environment and behavioral tendencies match. Introverted tendencies are found to be adaptive and health-promoting in unstable/changing environments that require sensitivity to stimuli while extraverted tendencies are adaptive in stable environments where sensitivity to stimuli is not required. When environmental conditions do

not match the predispositions, adaptiveness and health decrease (see Frost et al. (2013) and Thomas Bouchard's work).

Contemporary findings indicate that extraversion is a strong positive factor for many aspects of psychological and physical health. In particular, the extraversion facets of sociability (the enjoyment of engaging in social interaction) and positive emotionality are negatively related with anxiety, negative affect and mood, schizotypy, and social dysfunction. Additionally, extraversion often coincides with adaptive coping strategies (e.g. problem-oriented coping, social support) and greater well-being. However, extraversion is also a risk factor for negative health problems, as extraversion's assertiveness and experience-seeking facets highly correlate with externalizing problems (e.g. severe aggression, anger, conduct disorders) and bipolar disorder. Moreover, high extraversion is linked to narcissism and impulsivity.

Conversely, introversion shows moderate relations to anxiety, depression, chronic fatigue, and negative mental health risks such as self-blaming, shame, and low quality of life judgments. However, as preference for social interaction itself – a core component of the extraversion/introversion distinction – is not reliably related to morbidities, the inverse relation of the extraversion pole with neuroticism at least partially drives the introversion pole's relations to anxiety and negative affect-based health problems. Therefore, more explicit definitional boundaries between extraversion, introversion, and neuroticism are called for to better understand each concept's unique health effects.

Agreeableness

Part of the five- and six-factor model of personality, agreeableness – the predisposition to be socially acceptable, trusting, and considerate – is predominantly health-promoting. Agreeableness is positively associated with self-reported sense of well-being and negatively related to depression and suicidality, externalizing problems, and pathological narcissism and psychopathy. Physically, agreeableness reduces the risk of stress, high blood pressure, and other cardiologic problems. Post illness or trauma, agreeableness also promotes adaptive coping via agreeable individuals possessing greater social support. However, researchers have recently noted that most measures of agreeableness systematically examine only positive aspects of agreeableness; contemporary personality measures have since identified maladaptive components of agreeableness that result in increased risk of obsessive–compulsive personality disorder (OCPD) as well as dependent personality disorder (DPD; see Samuel & Gore, 2012).

Openness to Experience/Intellect

Openness is contemporarily recognized as a trait consisting of two conjoined but distinct concepts: openness – the tendency to seek out novel stimuli or experiences, and to be flexible and imaginative – and intellect – general cognitive tendencies related to information processing. However, most measures rarely explicitly separate the concepts. Like the previous traits, this complex super-construct has mixed effects on health. Meta-analyses indicate

that openness is largely unrelated to many clinical symptoms, sense of well-being, life satisfaction, and aggression. However, research does indicate some major influences of openness on psychological health.

Overall openness (openness and intellect conjoined) increases the risk of negative affect and mood disorders, such as seasonal affective disorder, via a reduction in neural sensitivity to serotonin (the compound in the brain that stimulates happiness and euphoria). Additionally, several facets of openness (eccentricity, perceptual dysregulation, and unusual beliefs) positively relate with DSM-IV "psychopathy". When separated, openness alone (without intellect content) positively predicts psychopathy, and schizotypal personality disorder, though to a lesser extent than neuroticism, extraversion, and agreeableness. In contrast, openness can also promote positive affect, and protect against anxiety-based disorders such that high openness prevents neurotic tendencies from actualizing into clinical anxiety and fear. Moreover, intellect negatively predicts schizotypal disorder and psychopathy. In terms of coping, openness promotes both adaptive and maladaptive strategies such as wishful thinking and escapism. This complex set of results is likely due to the current lack of measurement separation between the openness and intellect concepts.

Conscientiousness

Conscientiousness – defined as the predisposition to plan, strive, persist toward goals, and be responsible – is primarily a beneficial trait that augments good health. Specifically, conscientiousness is regularly related to primarily adaptive coping (though disengagement – a negative, maladaptive strategy – is often also employed to suppress negative thoughts). Conscientiousness is related to reduced substance use, internalizing (e.g. depression, anxiety) and externalizing problems, neuroticism-generated distress, and psychopathy. Furthermore, conscientiousness promotes sexual function and healthy living routines, increasing longevity and sexual health. Conscientious individuals are also more likely to engage in positive health behaviors (e.g. physical activity) and experience fewer health complications. Socially, conscientiousness enhances relationship maintenance, bolstering longevity and well-being through the promotion of a stable social network. However, some researchers have noted that maladaptive components of conscientiousness – also under-measured in most psychometric inventories – display the same increased risk of DPD and OCPD as agreeableness.

Honesty-Humility

The sixth factor of Lee and Ashton's HEXACO model of personality, honesty-humility is a joint trait representing the predisposition toward modesty and truthfulness. Though few physical health benefits are derived from honesty-humility, this characteristic is a positive factor involved in psychological stability. Specifically, honesty-humility enhances self-awareness, co-operation with clinicians, and health management when undergoing treatment. Additionally, antisocial tendencies such as the Dark Triad of personality (narcissism, Machiavellianism, and psychopathy; Paulhus & Williams, 2002) are reduced considerably

by honesty-humility, explaining a large portion of people's variation in these negative tendencies. Risk-seeking is also inhibited by honesty-humility. However, high honesty-humility can also promote guilt, which may become harmful if extreme.

Trait Emotional Intelligence

Trait emotional intelligence (TEI) exists at lower levels of personality hierarchies and is the self-perception of one's emotion-related facets. TEI has been shown to relate more strongly to mental health than physical health. Nevertheless, studies have found some significant influences of TEI on both physical and mental health. Higher TEI has been associated with good general health, better physiological functioning, and more positive health behaviors, and has a negative relationship with depression. Benefits of high TEI for health may include being less affected by stress, being able to repair mood, social support, and its positive relationship to internal locus of control when it comes to health.

A Valuable Avenue

Complementary to the traditionally emphasized biological and environmental determinants of health, research shows that personality factors also possess a considerable role in determining physical and mental health states, treatment recommendations and effectiveness, and long-term health outcomes. Therefore, personality offers clinicians and other health professionals another valuable avenue for explaining and predicting health.

Honesty

Ken J. Rotenberg

Keele University

Conceptualization and Categorization

Honesty has been the focus of psychological research from the very beginning of the discipline until the present. As with many topics examined by psychological researchers, people have an intuitive understanding of the construct of honesty. Most dictionary definitions highlight that honesty comprises truthfulness, sincerity, and frankness and the absence of deceit or fraud. Broadly, honesty entails truthfulness, sincerity, genuineness, the absence of cheating, the absence of deception, and the absence of stealing. In addition, honesty is an aspect of the Honesty-Humility (H) dimension of the HEXACO Personality Inventory. According to the Bases, Domains, and Targets trust framework (BDT; Rotenberg et al., 2010) there are three domains of honesty: (1) cognitive/affective which comprises individuals' beliefs, feeling, as well as understanding of honesty (*honesty beliefs*), (2) behavior-dependent which comprises depending upon others to be honest (*behavior-dependent honesty*), and (3) behavior-enacting which comprises engaging in honesty behaviors (*honesty trustworthiness*). This BDT framework will be used to summarize the work on honesty.

Honesty Beliefs

When in the course of development are individuals capable of holding honesty beliefs? One of the earliest works on the topic was carried out by Piaget (1965/1932) who found that young children (≤9 years) based their judgments of lying on the severity of the act (i.e. the amount of damage caused by the "lie") rather than on the intentions behind the act. This form of *moral realism* was replaced in older children by *moral subjectivism* which involved reliance on the intentions guiding the act rather than severity of consequences of it. Contemporary researchers have found that Piaget underestimated the capacity of children and have found that young children show a substantive appreciation of the intentions behind the act. For example, it was found that even 4-year-old

children reward story characters for their positive intentions even when the characters' communication had resulted in falsehoods and caused harm.

Theory of Mind (TOM) ability is required for children's cognitive/affective honesty. In order for children to hold honesty beliefs, they need to understand that others can be motivated to cause others to have false beliefs (i.e. as an attempt to fool others). In particular, children need to comprehend the perception, intentions, and emotions of others in the service of understanding that a person can cause another to hold false beliefs. Children as young as 3 years of age have been found to demonstrate first-order TOM ability comprising the fundamental understanding that others hold distinctly different perceptions, intentions, thoughts, and emotions from their own. By acquiring this ability, it is possible for children to establish stable individual differences in holding honesty beliefs.

Research converges in showing that children at a very early age (3 or 4 years) morally condemned lying as well cheating and stealing. Nevertheless, researchers have found that those judgments are affected by cultural differences and the nature of the lie. It has been found, for example, that Chinese children are more acceptant of lying done to protect others' feelings or the reputation of the group than are North American children. Furthermore, across childhood, children increasingly evaluated others' lying in politeness situations less negatively and were more inclined to tell that type of lie (see Xu, Bao, Fu, Talwar, & Lee, 2010). Furthermore, research shows that adults from Western cultures view altruistic lies as more moral than they do selfish honesty (Levine & Schweitzer, 2014). In practice, children and adults do not typically exceed chance levels in detecting when persons lie. Children and adults often rely on erroneous cues to detect lying such as the misguiding cues of avoidant gaze and rapid limb movements.

There is evidence that individuals' honesty trust beliefs in others are modestly stable across different periods in development and therefore serve as a modest personality disposition (Rotenberg et al., 2010). Research supports the conclusion that there are consequences of that disposition. When honesty beliefs are part of a broader array of trust beliefs, then they predict psychosocial and health functioning such as prosocial behavior, low loneliness, low aggression, and good physical health.

Behavior-Dependent Honesty

Behavior-dependent honesty has been examined in a series of studies by Harris and colleagues (see Harris, 2012). These researchers presented 4- and 5-year-old children with figures depicting hybrids of animals (i.e. they had features of two animals). Mothers or others provided names for the animals. This paradigm is designed to assess whether children will depend on others as sources of knowledge. The researchers have found that children select the name of the animal provided by: (1) their mothers when the object was a complete hybrid; (2) an adult source who had a history of accuracy, (3) adults who showed consensus regarding the name and (4) when the race of informants was the same as the children's. It was found, though, that when the hybrid animal distinctly had features of one animal rather than another (it was not a complete hybrid), then children would select the corresponding name even when the mother provided another name for the animal.

The findings may be taken to suggest that young children depend on others as honest sources of information when the persons are their parent, same-race, and demonstrate a

history of accuracy and agreement with others. Nevertheless, young children demonstrate an independent grasp of reality because they do not override reality simply because of what others say. According to Harris (2012) these findings provide an insight into how children learn about the various facets of the world such as the principles of science and religion. One limitation of the work by Harris and colleagues is whether the "honesty" behavior (i.e. selecting a name) in the research is indicative of children's perceptions that persons are intentionally telling the truth as opposed to deceiving them.

The preceding patterns are further qualified by one principle. Individuals who hold too high trust beliefs in others (e.g. depend on others to always tell the truth) show an elevated risk of psychosocial maladjustment. Individuals who are too trusting deviate from social norms and are vulnerable to being betrayed. As a result they tend to experience psychosocial problems.

Honesty Trustworthiness

Is there evidence of honesty trustworthiness as a personality characteristic? Research carried out early in the disciple of psychology (e.g. Hartshorne & May, 1928) showed that there were low correlations (average .23) among 33 different tests of three types of deceit in children (cheating, lying and stealing). The findings were not supportive of the conclusion that honesty was a *highly coherent* personality characteristic. The researchers did find stronger correlations among the tests of deceit in similar situations (e.g. in tests of cheating in the school room). These findings support the notion that the relations among cheating, lying, and stealing are constrained by context and that may be viewed in contemporary theory as supporting a *trait x situation* personality approach. Individuals are prone to be dishonest but their behavior is still modified by, and depends upon, the social situation.

Children demonstrate lying and cheating when they are very young (i.e. 3 and 4 years of age). Lying and cheating increase until the elementary school year period. Lying is not consistent during the early school years (5, 6, and 7 years) but becomes modestly stable across the middle childhood years (Gervais, Tremblay, Desmarais-Gervais, & Vitaro, 2000). Research on the Honesty-Humility (H) dimension of the HEXACO Personality Inventory supports the notion that honesty trustworthiness, as well as behavior-dependent honesty, are personality dispositions.

Research shows that there is a wide range of negative consequences of dishonesty that emerges during childhood. Lying during childhood is predictive of disruptive behavior and delinquent behavior. When lying is included in broader measures of conduct disorders (cheating and stealing) then that form of dishonesty during childhood predicts criminal offending, mental health disorders (specifically depression), substance dependence, and relationship and parenthood issues in late adolescence and early adulthood.

Summary

From an early age (3 or 4 years), children: (1) show an understanding of lying, (2) establish honesty beliefs regarding others which are modesty stable; (3) morally condemn dishonesty although that varies by culture and benevolence of lying, and (4) show behavior-dependent honesty which is constructed from social interaction but constrained by physical

reality, (5) show honesty trustworthiness (lying, cheating and stealing). Also, research shows that individual differences in those behaviors demonstrate some stability across development and therefore serve as modest personality dispositions. There are a multitude of consequences of the different domains of honesty which include the psychosocial functioning, mental health, and physical heath.

Hopelessness

Chloe Lau and Callista Forchuk

University of Western Ontario

What is Hopelessness?

Hopelessness is considered a cognitive risk factor in the development of depression. This construct is characterized by two core expectations: (1) that negative events will occur, or that positive events will not occur (i.e. negative outcome expectancy), and (2) that no amount of effort can influence the onset of these events (i.e. helplessness expectancy; Abramson, Metalsky, & Alloy, 1989). Essentially, the hopeless individual believes that she is powerless in changing current and future adverse circumstances.

Hopelessness Theory of Depression

According to the hopelessness theory of depression, hopelessness is a proximal and sufficient cause of depressive symptoms, such that the presence of this etiological factor is proximate and guarantees occurrence of depressive symptoms (Abramson et al., 1989). The hopelessness theory of depression was formulated to address limitations on Seligman's (1972) learned helplessness theory of depression, which posits helplessness will develop over the occurrence of repeated, inescapable aversive circumstances. While the latter theory illustrates the development and maintenance of depressogenic cognitive styles, it does not account for the individual differences in the vulnerability to hopelessness. The hopelessness theory of depression posits that it is the interaction of depressogenic inferences and negative life events that leads to the development of depression. Hopelessness is considered one link in a chain of cognitive diatheses, ultimately predisposing an individual to depression, given the experience of negative events. At the distal end of this chain is a general tendency for an individual to form three types of negative inferences regarding an undesirable event: (1) the event is stable over time (i.e. stability), (2) undesirable consequences will occur and are widespread over time (i.e. globality),

and (3) negative charactersitics are attributed to the self (i.e. internality). These three negative inferential styles are considered depressogenic tendencies, as they function as cognitive diatheses for hopelessness and ultimately for depression. Furthermore, individuals may be trapped in a self-regulatory cycle, as depressogenic explanatory styles may create less successful resolutions, thus fostering further negative beliefs. Overall, by categorizing hopelessness as a proximal cause in a sequence of etiological events, theorists place hopelessness in close proximity to the development of depression.

Several theories have been generated to resolve the limitations of the hopelessness theory of depression. First, although findings in adult and adolescent populations have supported this etiological chain of events, mixed findings were revealed in the youth literature. To resolve this issue, the "weakest link hypothesis" was proposed, stating that individuals are as vulnerable to depression as their most negative inferential style. Essentially, each of the three depressogenic tendencies is examined separately in previous research, without considering the relations between them. Thus, the most prominent negative inferential style acts as a cognitive diathesis, and would foster hopelessness in the event of a negative stressor in children. The three tendencies tend to be distinct from each other at an early age but consolidate to form a singular cognitive vulnerability in older age groups. Second, individuals differ in vulnerability to developing negative inferential styles in social and professional areas, which is referred to as the specific vulnerability hypothesis. The specific vulnerability hypothesis explains that an individual will become most vulnerable to hopelessness and depression when a negative event occurs which matches the vulnerability domain he is susceptible to. Lastly, researchers recognized that by examining cognitive vulnerability and negative events as categorical events (i.e. occurrence vs. non-occurrence), individual differences in severity of both cognitive vulnerability and negative events are lost. The titration model addresses this limitation in the hopelessness theory of depression, as it states that an individual with greater depressogenic tendencies will require a less substantial negative event for specific negative inferences to occur, and for hopelessness and depression to follow. In contrast, an individual with less cognitive vulnerability will require a more impactful negative event to produce hopelessness and depression (Abramson et al., 1989).

Hopelessness as a State or Trait

Relative stability is a required characteristic of cognitive diatheses. This has prompted investigation into the extent to which hopelessness should be categorized as a state or trait. Hopelessness may be conceptualized as both a state, when negative expectancies accompany current situations as a transitory experience, and as a trait, when negative expectancies become chronic response patterns. Most empirical findings support that hopelessness is a trait-like characteristic, as negative inferential styles are relatively stable over time. This is supported by the finding that individuals recovering from depressive episodes show elevated levels of negative inferential styles compared to groups without a prior history of depression. These findings suggest that negative inferential styles have long lasting effects, even after depressive symptoms subside. Despite this relative stability, changes in depressogenic tendencies are adaptable through treatment.

Meta-analytic findings on psychotherapy for depression indicated that therapeutic interventions (1) reduce the tendency to form negative inferences and (2) reduce hopelessness ratings post treatment.

Risk Factors of Hopelessness

While cognitive vulnerability is necessary for hopelessness, it is not sufficient to produce hopelessness in the absence of a negative event, which can be triggered by early environmental stressors. Specifically, chronic emotional maltreatment reinforces existing depressogenic causal attributions, leading to the development of trait-like hopelessness. Interestingly, negative causal attributions are formed more easily in emotional abuse than physical and sexual abuse, as the perpetrator reinforces greater depressogenic attributions in the former event. Hence, childhood emotional abuse, but not sexual or physical abuse, acts as a developmental antecedent to negative inferential styles.

Familial and peer emotional victimization also predicted negative attributional styles in adolescents, contributing to higher levels of hopelessness. The interaction of threatened self-worth and negative stressors (e.g. bullying) leads to the development of hopelessness through internalized beliefs of worthlessness and a negative sense of self within the victim's self-schema. Furthermore, victims experience an external locus of control, and a sense of helplessness regarding one's ability to alter present circumstances. Loss of control may be one mechanism through which emotional abuse and victimization contributes to hopelessness.

Other etiological factors, such as economic difficulties, unemployment, lower levels of education, and posttraumatic symptoms, have been consistently found to be associated with greater hopelessness.

Protective Factors Against Hopelessness

Protective mechanisms can prevent the development and maintenance of hopelessness. For instance, victimized adolescents with stronger future orientation were more optimistic, envisioned a better future, and were subsequently less hopeless. These findings indicate that adolescents who engaged in future-oriented thinking may disengage from ruminating about stressful circumstances at present, and may envision a future different from the present. This type of thinking acts as a protective factor against subsequent depressive symptoms and suicide-related behaviors.

The significance of social support and community is also recognized. In particular, adolescents who lived in neighborhoods with weak social networks reported higher levels of hopelessness, even when controlling for socio-economic status and depressive symptomatology. The theory of adaptive inferential feedback may illustrate how positive social support influences hopelessness. In this theory, members of the victim's social group facilitate positive evaluation of the self, world, and others through correcting the victim's negative inferential styles. This act leads to a positive sense of self and greater self-confidence for the victim of negative inferential styles and thus, hopelessness.

Personality Correlates of Hopelessness

Hopelessness is more commonly associated with certain personality traits than others. In particular, higher neuroticism, lower levels of conscientiousness, and lower levels of assertiveness and positive emotions are associated with greater hopelessness. Findings of positive associations of hopelessness and neuroticism are consistent with the literature suggesting neuroticism is positively associated with suicidal ideation in both clinical and community samples.

Measurement of Hopelessness

The Beck Hopelessness Scale (BHS; Beck, Weissman, Lester, & Trexler, 1974) is the most widely administered quantitative measure of hopelessness, demonstrating strong psychometric properties in psychiatric inpatient, outpatient, community, and cross-cultural populations. The total BHS score is a sum of item responses ranging from 0 to 20, with higher scores indicating greater frequency and severity of pessimistic beliefs and expectations of being beyond hope and help.

Psychiatric studies using the BHS demonstrated the measure has strong convergent-discriminatory properties, such that psychiatric patients scoring 9 or higher (i.e. representing moderate to high hopelessness) were 11 times more likely to complete suicide than patients scoring 8 or lower (i.e. representing normal to mild hopelessness). Moreover, moderate to high scores identified almost all patients with suicide attempts. These scores are a better predictor of attempted suicide and self-harm than other correlates, including diagnosis of depression, history of sexual abuse, and past suicide attempt.

Other measures of hopelessness include the Cognitive Style Questionnaire, developed to measure negative inferential styles, and the Kazdin Hopelessness Scale and Geriatric Hopelessness Scale developed to measure hopelessness in children and older adults respectively.

Clinical Predictors and Treatment of Hopelessness

While hopelessness is not a psychiatric disorder, hopelessness depression has been proposed as a distinct symptom profile that develops based on this chain of cognitive diatheses. However, evidence for this subtype of depression is mixed, with consistent support for distinct cluster symptoms, yet these symptoms show poor internal reliability.

Clinical guidelines suggest that hopelessness should be thoroughly assessed as it predicts number of suicidal attempts, severity of impulsive attempts, and greater wish to end one's life. Assessment of hopelessness can also influence decisions regarding appropriate treatment protocols for depressed patients. For instance, hopelessness is positively associated with greater treatment response to antidepressant medications in treatment-resistant depression.

Cross-Cultural Differences in Hopelessness

Hopelessness has been identified in cultures across the world. Overall, cross-cultural replications demonstrated positive associations between hopelessness, depressive symptoms, and suicidal ideation across genders and cultures. Interestingly, American undergraduates scored lower on the BHS compared to students of other countries and this finding was replicated with adolescent samples. Furthermore, a significant trend toward greater hopelessness scores from 1978 to 2010 was identified in American undergraduates, but this finding was not replicated in the adolescent sample (Lester, 2015).

Future Directions for Research on Hopelessness

Despite the considerable research and support that hopelessness has received, there are areas left to be explored. First, more evidence is needed to investigate the mediating role of hopelessness in this cognitive chain of events in the hopelessness theory of depression. Future studies are needed in order to clarify the role of hopelessness as a cognitive diathesis. Second, researchers have suggested that the true or false format of the BHS presents a major limitation. Some researchers have suggested changing the item response to a Likert scale system (e.g. strongly agree to strongly disagree) to increase variability in responses. Lastly, the hopelessness theory of depression exists alongside other cognitive-diathesis models of depression, which prompted researchers to question whether hopelessness and negative inferential styles are unique predictors of depression and other clinical outcomes. Furthermore, negative inferential styles have been considered conceptually similar to Beck's dysfunctional attitudes and negative self-schemata, and Nolen-Hoeksema's rumination, as outlined in the response styles theory. Future research should investigate whether these constructs may be interchangeable.

Hostility, Personality Correlates of

Clara S. Lee and Joshua S. Bourdage

University of Calgary

Hostility is associated with a host of phenomena, such as anger, aggression, and cynicism, etc., and as such, varying definitions of hostility have been proposed. Previously, hostility was conceptualized as an attitudinal construct characterized by the dislike and negative evaluation of others, as well as the motivation for aggressive and often vindictive behavior. Currently, hostility is regarded as a more multifaceted construct, comprising cognition, affect, and behavior.

The cognitive component of hostility is often viewed as the main characteristic aspect of the hostility construct, and it constitutes having negative beliefs about others. As such, there is often a high amount of agreement with statements that describe others as untrustworthy, undeserving, and immoral. Resulting from these cognitions are attributional biases, aptly named hostile attribution bias, wherein the actions of others are construed as involving aggressive intent. This is often then used as justification for the hostile person's own antagonistic actions. While hostile attribution bias is directed toward specific persons whose actions are antagonistic toward oneself, cynicism involves negative beliefs about human nature in general, and may also result from the cognitive component of hostility.

The affective component of hostility includes anger, annoyance, resentment, disgust, and contempt. Several researchers maintain that the angry affect is a consequence of prior hostile cognitions. The behavioral component of hostility is composed of aggression. Verbal aggression and other forms of antagonistic behavior are more frequent than overt physical aggression and can be expressed in subtle ways that do not violate societal norms. The cognitive, affective, and behavioral aspects of hostility are undoubtedly associated with each other, but it is not necessary for them to occur together. For instance, cynicism, anger, or antagonistic behavior can be present in the absence of the other two.

Scales Measuring Hostility

Several methods have been developed to measure hostility, including interviews and self-report surveys. The Buss-Durkee Hostility Inventory, one of the most widely used self-report surveys, was developed by Arnold H. Buss and A. Durkee in 1957. The BDHI measures a number of various subhostilities that make up hostile and aggressive behaviors. These subhostilities include Assault, Indirect Hostility, Irritability, Negativism, Resentment, Suspicion, and Verbal Hostility. The BDHI is widely used although some research seems to indicate that it may not assess a unitary hostility construct. The successor of the BDHI is the Aggression Questionnaire (AQ) which consists of four scales that measure Anger, Hostility, Verbal Aggression, and Physical Aggression. With this, it was found that men had higher scores on Physical Aggression, Verbal Aggression, and Hostility, but not on Anger.

Another frequently used inventory is the Cook-Medley Hostility Scale, developed by W. W. Cook and D. M. Medley in 1954, which was originally developed to assess teachers having difficulty getting along with their students. Beginning in the 1980s, the Hostility Scale was used to assess the relationship between hostility and health outcomes. Items on the Hostility Scale are grouped into six subscales, including Hostile Attributions, Cynicism, Hostile Affect, Aggressive Responding, Social Avoidance, and Other. The Hostility Scale seems to be an adequate predictor of anger and hostility-related changes during frustrating situations, although not of violence potential. In addition, subsequent research indicates that the Hostility Scale is consistently correlated with characteristics outside the conceptual definition of hostility, such as anxiety and depressive symptoms.

A relatively recent technique for rating hostile behavior was developed in the form of a structured interview. The Interpersonal Hostility Assessment Technique (IHAT) rates hostile behavior on the basis of the style, rather than the content, of responses. These categories of response include direct challenges to the interviewer, indirect or more subtle challenges, hostile withholding of information or evasion of the question, and irritation. The IHAT has been found to be fairly reliable, correlating with other measures of hostility and being associated with expressions of disgust and anger.

Hostility and Broad Personality Frameworks

A common conceptual framework is important when defining specific dimensions of a particular trait and the part it plays in the psyche. Uniform measurement evaluation techniques are also important for establishing the similarities and differences among scales and between hostility and other traits. The Five Factor Model (FFM) of personality offers this opportunity by providing a common organizational framework to explain hostility, and its association with other traits.

Within the FFM, both anger and hostility are positively associated with Neuroticism, with correlations ranging from 0.2 to 0.6, and negatively associated with Agreeableness, with correlations ranging from −0.3 to −0.4. An overlap in content has been found between measures of the FFM and measures of trait anger and hostility. For instance, a facet of the Neuroticism dimension includes Hostility, while two facets of the Agreeableness

dimension are Trust and Compliance, which relate to the cynicism and hostile attribution bias defining hostility. In fact, the trait of Agreeableness has been traditionally visualized as a spectrum of Friendliness/Hostility. In a similar manner, the more recent six-factor HEXACO personality model also finds hostility to fall within low levels of Agreeableness. This is logical since a facet of Agreeableness from the HEXACO model includes Gentleness, where low scorers are critical in their evaluations of others.

The Interpersonal Circumplex (IPC) also has strong ties to hostility. One of the dimensions in the IPC is friendliness versus hostility, while the other is dominance versus submissiveness. The IPC can describe specific social stimuli, social responses, features of the social environment, and individual differences in social behavior. Personality psychologists Paul D. Trapnell and Jerry S. Wiggins suggested in 1990 that the friendliness versus hostility dimension can replace Agreeableness in the FFM, while the dominance versus submissiveness dimension can replace Extraversion due to their close correlations. With this, the IPC provides a useful framework with well-established assessments for validating hostility scales when combined with the other three FFM traits. Personality researchers Timothy W. Smith and Linda C. Gallo in 1990 found that Trait Anger, Hostility, Verbal Aggression, and Physical Aggression from the AQ correlated with the cold and unfriendly style of IPC hostility. In addition, Trait Anger and Hostility were more closely related to neuroticism than were Verbal and Physical Aggression.

The IPC can be used to explain the development of a hostile interpersonal style. For instance, from a developmental perspective, individuals may model behavior they had first observed in their parents or guardians during childhood. Moreover, they may internalize, such that the development of representations of self, others, and relationships forms the basis of generalized interpersonal expectancies. Finally, there may be introjection insofar as people treat themselves in ways they were treated by key developmental figures. This is closely related to attachment theory where attachment styles such as secure, anxious, and avoidant are influenced by parenting styles. Over time, these transactional cycles would contribute to continuities in personality and even foster a health-relevant trajectory. For instance, continuous negative social interaction sequences would promote exposure to unhealthy social contexts such as isolation or conflict.

Hostility and Health

Hostility has been consistently associated with coronary heart disease (CHD) and premature mortality in both men and women, and it has been suggested as a risk factor. Suggested mechanisms that explain this association include the Psychophysiological Reactivity Model. The model hypothesizes that hostility contributes to the risk of CHD through exaggerated cardiovascular and neuroendocrine responses to potential stressors, such as increased blood pressure, heart rate, and adrenaline. However, recent research has suggested that an impaired physiological recovery from stressors may contribute to risk factors as much as heightened reactivity.

Another model explaining this relationship is the Psychosocial Vulnerability model, where hostile persons report greater levels of interpersonal conflict and stress, along with lower levels of social support. These psychosocial vulnerabilities could mediate the

associations between hostility and health where hostile individuals would be exposed to more of these vulnerabilities than non-hostile individuals, resulting in poorer health. This may lead to a behavioral pattern that in the long run would further increase conflict and decrease support.

Finally, it has been suggested that more hostile individuals have a less healthy lifestyle with more drinking and smoking, resulting in the association with subpar health. In order to reduce health risks, the early improvement of physical health is recommended.

Treatments

With the incorporation of interpersonal theory, early prevention measures are also recommended, with prevention of aggressive behavior and poor peer relations in childhood and adolescence. A variety of cognitive and behavior interventions can also be used to reduce anger and aggressiveness, where the average cognitive therapy recipient is better off than 76% of untreated subjects. It has been found that this was as efficient as blood pressure medication in reducing cardiovascular responses. Cognitive therapy was also found to result in anger reductions in abusive parents. According to the interpersonal theory, this will also have profound effects on the child where otherwise, the child would imitate the parent in their hostile interactions.

Impulsivity

Laura K. Flanigan and Emma A. Climie

Werklund School of Education, University of Calgary

Impulsivity is the tendency to act without forethought or consideration of potential consequences. Impulsive drives or actions can be seen as either non-functional (i.e. no intended benefit) or functional (i.e. with intended benefit). Non-functional impulsive actions can result in risky or inappropriate behaviors that may harm the individual or those around them (e.g. diving into a lake without first checking the depth); conversely, functional impulsive tendencies may be viewed as bold or courageous (e.g. diving into the same lake to save a drowning friend). Regardless of the functionality, impulsivity involves three separate constructs: the tendency to act without forethought, the focus on seeking novelty, and an emphasis on short-term over long-term benefits (Fino et al., 2014).

Impulsivity is associated with numerous brain areas, but has a specific association with the prefrontal cortex (PFC), which is the primary area of the brain involved in executive functioning, or the ability to plan, organize, and execute daily life activities. Lesions found in the nucleus accumbens and/or amygdala, associated with feelings of pleasure and the fight/flight response respectively, are associated with increased preference for short-term, immediate rewards. Damage to the PFC and/or right inferior frontal gyrus areas of the brain has been associated with behavioral disinhibition and impulsivity.

Theoretical Frameworks

Executive Functioning/Inhibitory Control

Impulsivity is often viewed as a deficit or difficulty with executive functioning and/or inhibitory control. Executive functioning is a set of supervisory mental functions that control cognitive, emotional, and behavioral responses. These executive functions include abilities such as working memory, reasoning, problem-solving, planning, and, most related

to impulsivity, inhibitory control. Inhibitory control is the ability to override a prepotent response in favor of a more adaptable or appropriate response (e.g. when playing "Simon Says," it is necessary to resist the urge to respond when the command does not start with "Simon says"). Impulsivity has been linked to a deficit in inhibitory control, where lower levels of inhibitory control are due to a slower inhibitory response, rather than a faster prepotent response. More specifically, those with impulsive behaviors tend to have a harder time stopping a behavior once it has started than preventing the behavior from beginning.

Self-Control

Self-control is the ability to control one's emotions and desires, especially when encountering challenging situations (e.g. seeing an ex-boy/girlfriend for the first time after a difficult break-up and remaining cordial). Individuals may demonstrate high levels of self-control which is related to a number of positive outcomes (e.g. academic achievement, psychological adjustment), or low levels of self-control which, as expected, is more closely related to negative outcomes (e.g. eating disorders, substance abuse, etc.). Low levels of self-control are also strongly related to impulsivity, as well as general impulsive behaviors (Hofmann, Friese, & Strack, 2009). Essentially, those who are low in self-control tend to demonstrate higher levels of impulsivity.

It has also been suggested that self-control can be viewed as a muscle (e.g. Baumeister, Vohs, & Tice, 2007), in that the more self-control is used, the more "tired" it becomes, thus increasing the amount of uncontrolled or impulsive behaviors. An example of this temporally depleting self-control would be the very common experience of coming home after a long day at work, during which eating habits were rigorously controlled, and eating an entire box of cookies. As self-control resources were "used up" during the day, late-night cravings become more challenging to overcome.

The abandonment of self-control can also be triggered by some form of failure. For example, in a phenomenon known in the eating literature as the "what-the-hell effect," people who are regular dieters who consume a "bad" food (e.g. a milkshake) will then subsequently consume more "bad" foods than their non-dieting counterparts who consumed the same milkshake (Herman & Mack, 1975). This suggests that impulsive behaviors may occur when self-control does not seem beneficial, or that it no longer matters.

Measures of Impulsivity

The measurement of impulsivity in individuals is typically done by health care professionals (e.g. psychologists). There are two primary means to gain an understanding of an individual's level of impulsivity: personality measures and performance-based measures. Personality measures typically involve rating scales completed by the individual him/herself or by a person familiar with the individual and his or her typical behaviors (e.g. parent, teacher). Performance-based measures examine an individual's actual performance on a task designed to test his or her impulsivity, rather than relying on paper-and-pencil answers to questions.

Personality Measures

Personality assessments or tests are very commonly used to examine trait (i.e. core personality characteristics) and state (i.e. current levels of functioning) impulsivity. Some of the more common assessment measures include the Barratt Impulsiveness Scale, Eysenck Impulsiveness Scale, Dickman Impulsivity Inventory, and the Lifetime History of Impulsive Behaviors.

Barratt Impulsiveness Scale

This scale is one of the oldest and most widely used impulsivity measures, consisting of 30 items and three subscales: Attentional Impulsiveness, Motor Impulsiveness, and Non-Planning Impulsiveness. These scales are further divided into six factors: Attention (focusing on the task at hand), Motor Impulsiveness (acting without thinking), Self-control (ability to plan and think carefully), Cognitive complexity (ability at challenging mental tasks), Perseverance (a consistent lifestyle), and Cognitive Instability (thought insertion and racing thoughts). This measure is frequently used with an adult population.

Eysenck Impulsiveness Scale

This questionnaire contains 54 yes/no items, consisting of three subscales: Impulsiveness, Venturesomeness (awareness of the potential consequences of an action, but acting anyway), and Empathy (care or concern for others). This scale has been normed for 16–87 year olds.

Dickman Impulsivity Inventory

This scale utilizes Scott J. Dickman's theory that there are two types of impulsivity: functional impulsivity (quick decision making when it is optimal, such as catching a falling vase) and dysfunctional impulsivity (quick decision making when it is not optimal, such as buying a chocolate bar at the supermarket checkout). It consists of 63 items divided between these two constructs, and is unique in that a version to measure impulsivity in children has been developed.

Lifetime History of Impulsive Behaviors

This measure is a 53-item questionnaire designed to assess the lifetime prevalence of impulsive behaviors, rather than short-term impulsive tendencies, as well as the potential distress and impairment associated with these behaviors. This scale assesses six dimensions: impulsivity, sensation seeking, trait anxiety, state depression, empathy, and social desirability. It also includes scales to assess clinically significant impulsivity, non-clinically significant impulsivity, and distress/impairment of the impulsivity.

Performance-Based Behavioral Assessments

Performance-based assessments allow for an objective, observable measure of impulsivity, and while they are not sufficient diagnostic measures on their own, allow for a larger picture of the impulsivity difficulties. These include paradigms such as the marshmallow test, the Stroop task, Go/No-go tasks, and the Continuous Performance Task (CPT).

Marshmallow Test

This test, more formally known as the "delay of gratification paradigm," was developed in the 1960s to assess the self-control of preschoolers. A single marshmallow is placed in front of the child, and they are informed that if they wait to eat the marshmallow until the experimenter returns to the room, they will be given a second marshmallow, both of which can then be eaten. Follow-up studies determined that those who were able to wait for the second marshmallow attained higher educational achievement, had more positive social and coping skills, and many other positive factors.

Stroop Task

This task is designed to measure an individual's ability to inhibit a prepotent response. First, individuals are presented with a stimulus and asked to read a list of written color names printed in colored ink. They are then presented with a different stimulus page which has written colored names printed in different colored ink. Individuals are asked to name the color of the ink that the word is printed in, rather than reading the word. Ability is measured based on a comparison between the time to complete the first list and the time to complete the second list, and the number of mistakes made in each.

Go/No-Go Tasks

These tasks are used to assess sustained attention and inhibitory control. The participant is trained to respond a certain way to a stimulus (e.g. pressing a certain key on a keyboard); this is the "go" stimulus. On some trials, a designated "stop" stimulus will appear right before the "go" stimulus, signaling to the participant that they should inhibit their response to the go signal. Performance is measured based on the number of correct inhibited responses, and occasionally the reaction time to the stop signals.

Continuous Performance Task (CPT)

The CPT is a neuropsychological task used to measure sustained attention, which is frequently related to distractibility and impulsivity. The CPT involves start and stop signals, just as in the Go/No-Go task, and is specifically made to be long, repetitive, and essentially "boring." This measure assesses the participant's ability to stay focused and attuned during menial tasks.

Connection to Psychological Disorders

Impulsivity is a trait that is seen throughout a number of disorders and is frequently identified as a symptom in many child and adult diagnoses. Pertinent examples include Attention-Deficit/Hyperactivity Disorder, Impulse-Control Disorders, Substance Abuse, and Bipolar Disorder.

Attention-Deficit/Hyperactivity Disorder (ADHD)

ADHD is a psychological disorder characterized by symptoms of inattention, hyperactivity, and/or impulsivity. ADHD is among the most common childhood disorders and is associated with numerous life-long difficulties, including reduced academic achievement and performance, social rejection, and accident-related injuries. It is currently categorized into three subtypes: primarily inattentive, primarily hyperactive–impulsive, or combined type.

Symptoms of impulsivity are very common among those with ADHD, and include behaviors such as blurting out answers to questions, difficulty waiting their turn, interrupting others' conversations, and leaving their seat in situations where staying seated is expected (e.g. in a classroom).

Impulse-Control Disorders

These disorders fall into a group known as Disruptive, Impulse-Control, and Conduct Disorders, and are characterized by problems in the self-control of emotions and behavior. The three disorders that are most specifically related to impulsiveness are Pyromania (the inability to resist the urge to intentionally start fires), Kleptomania (the inability to resist the urge to steal, typically without a need for the item), and Other Specified/Unspecified Disruptive, Impulse-Control, and Conduct Disorders (a broad category that generally incorporates individuals whose behaviors violate the rights of others or who demonstrate significant conflict with societal norms or authority figures).

Substance Abuse

Substance abuse is characterized by continued use of a particular substance or group of substances despite significant physical, psychological, social, or financial problems resulting from the substance use. Impulsivity is a major component of substance abuse disorders. Individuals with substance abuse problems often have a preference for instant gratification and demonstrate lowered inhibitory control, which makes appreciating future consequences and overcoming environmental pressures (e.g. peer pressure) difficult. This combination not only makes initial substance use more likely, but also increases the chance of escalation into addiction and abuse. Similarly, people who are higher in impulsivity are more likely to stop treatment prematurely, have greater cravings during withdrawal, and to experience relapses than those lower in impulsivity. It is also important to note that substance abuse can work reciprocally with impulsivity, such that prolonged substance use can increase impulsivity, and vice versa.

Bipolar Disorder

Bipolar disorder is characterized by periods of elevated mood (usually referred to as mania or hypomania) followed by periods of depression. Impulsivity is a typical symptom of a manic or hypomanic episode, as individuals experiencing these episodes are often easily distracted, have "flight of ideas" (racing thoughts), and have excessive involvement in activities with potential negative consequences (e.g. sexual indiscretions, risky business involvements). It has been suggested that those with bipolar disorder have higher personality-based impulsivity, which provides a potential link between this disorder and substance abuse and suicide attempts.

Definition

Intuition is a non-deliberative mode of thinking, based on knowledge stored in long-term memory, mainly acquired via associative learning. The input is processed automatically, holistically, and without conscious awareness. The output enables fast and affectively charged decision-making, which is often expressed as a "gut feeling," but cannot be further explicitly articulated.

It is necessary to distinguish intuitions from closely related terms such as instincts, insight, and reinvestment. First, in contrast to instincts, intuitions are based on learned representations and not on evolutionary shaped responses. Second and in contrast to intuition, insights are achieved by conscious processes, i.e. by solving a mathematical problem which involves systematic reasoning. Finally, the construct of reinvestment is considered in relation to two components: the motor component, the stable tendency of a person to manipulate explicit knowledge by working memory in order to control body movements during motor output, and the cognitive component, the tendency to monitor decision processes and ruminate about past poor decisions. When drawing comparisons with intuition, reinvestment is not solely linked to cognition but also relates to the motor component and also occurs mostly in stressful situations. Research results indicate that deliberative persons have a higher reinvestment tendency than intuitive persons, thus suggesting an inverse relationship between reinvestment and intuition.

Central Theories

The theoretical background of modern intuition research is mainly based on dual-processing theories which aim to describe human information processing in terms of two distinct systems. These theories have evolved across many academic disciplines and applied fields and

although they have differing names and labels, they are structurally similar. Dual-processing theories have a common structure which differentiates between one system that is characterized by its automaticity, non-consciousness and speed (usually referred to as reflexive or System 1) and a second, slower, conscious and deliberative system (usually referred to as reflective or System 2). Within the dual-processing framework, intuition is considered to be part of System 1, which is also seen as associative and older in terms of evolutionary development. The majority of human cognition and behavior is assumed to build on a combination of the two systems. However, there are still many debates between dual-processing theorists which include whether there is a clearly distinctive activation based on certain variables, a parallel processing or first an automatic and second, only when necessary, a deliberative activation, i.e. if someone realizes that his/her intuitive reaction is not sufficient and therefore invests more cognitive capacities.

Attributes of Intuition

According to most conceptualizations, intuitions include the following four characteristics: First, intuitions are considered to be non-conscious information processes that are consequently not directly observable nor explicitly accessible. Second, intuitions are experienced in a holistic manner which means they are built on non-serial overall heuristics and associations. This aspect underlines the strong relationship between intuitions with one's individual learning experiences. Third, emotions seem to play an important role within intuitive judgments, which on the subjective level is often expressed as a (gut) feeling. Furthermore, neuroscientific research showed activation patterns in affect-related brain areas during intuitive decision-making, which suggests a link between intuition and affect. Finally, a key characteristic of intuitions is automaticity. In opposition to analytical and reflective cognition, the outcome of intuitions is easily and almost instantaneously accessible to the individual.

Types of Intuition

Following the consideration that there are distinctive divisions within System 1, there is also the assumption that intuition itself is not a unitary construct. Therefore, initial classifications have been proposed to identify different types of intuitions. For example, Pretz (2011) proposed a model which differentiates between affective, holistic, and inferential types of intuition which are related to the attributes of intuition above.

Effectiveness of Intuition

A growing body of research has assessed under which conditions intuitive decision-making might be effective or even superior to deliberative judgments. In contrast to former conceptions, there is increasing empirical evidence that intuitions can play a vital role in successful decision-making. As a result of their fast and heuristic nature,

intuitions can demonstrate their strength particularly in situations of uncertainty, in complex environments and under time pressure. These results are endorsed by various fields of research such as sports and management. Conversely, as they are based on learning processes, intuitions can also be misleading, i.e. in situations where the future may be significantly different from the past. Ultimately, successful decisions may involve both intuitive and deliberative decision-making which depend on various factors. One of these factors that received particular attention among scholars is expertise. Evidence suggests that intuitions tend to be relatively more effective when decision-makers have a high level of experience in a given domain. They could build up relevant and exact schemas which are mental structures categorizing information. It can be suggested that there is a U-shaped relationship between the availability of intuition and level of expertise. For example, at the first stage of the relationship, a novice's intuition relies on general and simple information processing which therefore promotes higher levels of intuition. In the next stage and with further learning, intuition becomes less available for the former novice because of the increase in rule-based knowledge. Finally, at the opposing end of the U, intuition becomes important again at the expert level, as the former novice has acquired fluent domain-specific knowledge and substantial experience. This kind of expert-intuition is considered as qualitatively different from the first stage and is characterized by extensive domain-specific knowledge, pattern recognition, and automaticity. Additionally to the level of expertise, research suggests that people differ inter-individually in their preferences to rely on intuitive judgments. Intra-individually, people tend to rely relatively more on intuitive judgments in situations of positive affect.

Methodology

As a result of its unconscious nature, empirical research on intuition has been rather limited. Researchers across a range of domains attempted to tackle this problem by developing a broad variety of very different methodological approaches and study designs. This aimed to access, describe, and measure intuition and its occurrences and outcomes in order to gain a comprehensive understanding of the construct. In contrast to the relatively large consensus on the main features of intuition, there is less agreement on the best approaches to encapsulate the concept of intuition empirically. In part, the diverging views on methodological approaches might be rooted in the diversity of the academic fields involved in intuition research. The typically preferred methods differ across disciplines which may also shape the individual foci that the researchers lay on specific aspects and types of intuition. Key methods to assess intuition in laboratory and/or field-based settings include direct instruction, self-report questionnaires, retrospective reports, incubational methods, scenario-based, neurophysiological approaches, and affective priming. When assessing different types of intuition, researchers developed self-report instruments focusing on specific facets of the construct. For example, Pretz et al. (2014) introduced the Types of Intuition Scale (TIntS), a self-report measure which assesses individuals' preferences for three types of intuition: holistic, inferential, and affective.

Fields of Application

Comprehensive knowledge on how intuitions function and when they are useful carries great potential for successful decision-making. As a result, the construct of intuition is examined across various contexts of application including everyday life, education, finance, sport, and global politics. For example, intuition seems to play a crucial role in professional sports where automaticity and efficient perception-action-emotion-cognition couplings are needed to enable fast reactions and produce successful performance under pressure. Also in sports, but not exclusively, there is increasing evidence for the take-the-first heuristic, which describes that when the individual has some expertise in the task, then the first intuitive option that "comes to mind" is usually the best one and any further generated option decreases in quality. In general, research on intuition is not limited to a specific domain but it is rather a global construct which can be applied to numerous contexts and fields of research. On the other hand, expert-intuition acquired in one specific domain, i.e. in tennis, is not considered to be automatically transferable to another domain, i.e. to handball or management decisions, which highlights the need for specific training and experience in a specific domain to develop one's intuition in this particular domain or field of expertise.

Critical Review

In the past, the construct of intuition had been considered as unreliable, unscientific, and sometimes even as spiritual mystification. In recent years, the construct has received increasing attention among scholars across many disciplines. To examine how intuitions work and to learn about their strengths and weaknesses has been the target of extensive studies. By now, there is general consensus on the importance of intuition in human decision-making, the main features of the construct, and the need for broad research on intuition. However, there is conflict surrounding methodological approach to intuition research. The common study designs, for example self-report questionnaires, might not be sufficient as it seems debatable whether a cognitive process that is considered as rapid and without conscious awareness can be measured in this way. Similarly, brain mapping might not be enough as other physiological factors are presumed to influence intuition as well, such as skin conductance and heart rate variability. Despite recent methodological advancements, i.e. more sophisticated designs, mixed-method approaches and the assessment of types of intuition, the measurement of the construct remains one of the biggest weaknesses in current research. However, the latest research from cognitive psychology examining the take-the-first heuristic has proven itself as a good starting point in terms of a clear operationalization of intuition that can be further connected to brain, physiological, and self-report measures.

Outlook for Future Research

Future research can aim to build on the convergent understanding of intuition and follow previous findings on the importance of the construct and the potential benefits of intuitive decision-making. A potential starting point for researchers would be to clarify

the definition and terms of intuition as this is currently still an issue within research. In order to address this issue, the wording proposed above provides a clear definition of intuition and may serve as a common working basis for future research. Nevertheless, it seems crucial to proceed with the different types of intuition in order to enable comprehensive research findings on the topic. It could be suggested that the biggest challenge still remains at the methodological level, with the measurement of intuition which is essential to underpin the construct. Therefore, further methodological insight is clearly demanded. Additionally, future studies should focus on the identification of different types of intuition in order to gain a deeper understanding of the underlying processes and facets of the construct. In summary, research and knowledge on intuition have great potential for a variety of applications and could really make a difference on the way to successful decision-making.

Independent Researcher and Policy Analyst

Mood

Mood refers to sporadic low to medium intensity states, lasting over minutes to days, which indicate different types of positive and negative affect. Examples of moods include happiness, surprise, anger, fear, and sadness. Moods are often manifested through physiological signals, including increased heart rate, perspiration, and behavioral signals like smiling, crying, and shouting. Moods are distinguishable from motivation since motivation, only, is debatably associated with goals. While the experience of a fearful mood, for instance, might cause an individual to seek help, the same emotion may be felt without the presence of such or any other goals. Moods are also distinguishable from emotions. Specifically, moods are not always caused by nor focused on a specific object or event, while emotions are caused by a specific object or event and focused on that object or event.

A common theoretical problem in assessing mood states is there are often no clear labels, definitions, or boundaries across the literature on mood states for different affects. For example, anxiety and other states are simultaneously referred to as emotions, mood states, or Big Five traits across scientific literature and lay language. This issue poses difficulties in comparing research findings and integrating literature, but is being overcome using data reduction techniques and a broad range of validity studies.

Regardless, the significance of understanding mood states for health professionals, researchers, students, and laypeople in the contexts of personality and individual differences is three-fold. First, traits of personality are related and viewed as aggregates of mood states in different situations. In other words, individual Big Five personality traits (i.e. extraversion, conscientiousness, agreeableness, neuroticism, and openness) influence how and how often different individuals experience moods. Second, mood states influence behaviors, regardless of individual traits. For example, the experience of anxiety may impair an individual's public speaking performance, independent of that individual's knowledge and ability, while sadness may influence an individual's interpersonal relations at a place of employment, regardless of that individual's personality or charm. Third, the

contexts in which mood states occur are important for understanding diagnostic mental health classifications. In most cases, feeling sadness after being married or excitement after failing a test deviates from normal emotionality and indicates potential mental disorders.

Theories on the Structure of Mood States

There are two popular ways of understanding the structure of mood. One dominant conclusion is that mood states are universally composed of two robust factors: positive affect and negative affect. Developed by Watson and Tellegen in 1985 and known as the Positive and Negative Affect Schedule (PANAS), this structure is demonstrated across all major lines of research on affective structure, as well as studies on self-reported mood, words used to describe them, and facial expression analyses. The PANAS describes affects as high and low positive, as well as high and low negative. Examples include pleasant mood states like happiness and excitement; mood states of engagement like surprise, anger, and arousal; mood states of disengagement like quiet and calmness; and mood states of unpleasantness like sadness, anxiety, fear, and irritability.

Another dominant conclusion describes mood states in terms of three dimensions: energy versus fatigue to describe positive affect, tension versus relaxation to describe negative affect, and happiness versus unhappiness, which is not linked to physiological arousal, but is a purely psychological state. This method of understanding mood states was developed by cognitive psychologists who were critical of the PANAS, like Matthews, Jones, and Chamberlain in the 1980s and 1990s, and Schimmack and Grob in the year 2000. Instruments used to measure the three mood dimensions include the UWIST Mood Adjective Checklist by Matthews and company and the Multidimensional Mood Questionnaire (MDMQ) by Steyar, Schwenkmezger, Notz, and Eid.

Although numerous studies have successfully replicated positive affect and negative affect as the basic dimensions of mood, other studies critique their definitions and universality. For example, some cross-cultural studies showed that even though expressions like "I feel bad" or "I feel good" can be found in all languages, some languages have no specific equivalent words for "fear" and "anger." Research on mood states also declined at the beginning of the Big Five era and the popularity of dispositional approaches in the early 1990s. Despite the decrease in studies on mood states, there has been an increase of research on topics like affect in human performance and individual differences in abilities to identify and manage moods.

Individual Differences in the Experience of Mood

A great deal of research suggests that moods are interpreted as and explained by personality traits. Studies that influenced and were influenced by the works of Watson and Clark examined longitudinal stability of measures of mood. They found that individuals' moods are relatively consistent overtime. Other studies found, for example, correlations between negative mood and neuroticism, as well as positive mood and extraversion. A converse theoretical position holds that a substantial percentage of mood variance

cannot be explained by personality traits. An example includes the works of Eysenck and Eysenck, who expected phlegmatic individuals to display the least variability in mood states and choleric individuals to display the most erratic mood states. Phlegmatic individuals refer to those identified as being low in both neuroticism and extraversion, while choleric individuals are those identified as being high in both neuroticism and extraversion. A conciliation of the two positions is that high neuroticism, alone, is the best predictor of mood variability.

Irritability

Irritability is defined as a normal, yet adverse negative affect that can be triggered by a range of daily inconveniences, including relational disagreement, or conflict, physical pain, noise, hunger, or even heavy traffic. Most people experience the behavioral manifestations of irritability at least occasionally during the life course. Such responses lie between the spectrum of moods of displeasure and disengagement and may encompass observed or unobserved manifestations of annoyance, anger, impatience, and temper outbursts. Synonymous terms include moodiness and irritable mood. Chronically high levels or frequent episodes of irritability are associated with a range of underlying medical/physical or mental disorders in children, adolescents, and adults. One of the leading authorities on irritability and its associated impacts is the American Psychiatric Association (APA), which has included irritability in depressive, generalized anxiety, and disruptive behavior disorders diagnoses of the Diagnostic and Statistical Manual of Mental Disorders (DSM) since 1952. According to the APA and other authorities on the subject, severe irritability has received little attention in research. However, its prevalence and impacts on healthy and ill populations, vis-à-vis relationships and overall quality of life, prompt the need for further research on its consequences and treatments.

Similar to the issue of mood state definitions, research on irritability is often hindered by the lack of homogeneity in its definitions. Within the medical profession and lay language there is also a lack of differentiation of the term "irritability" from such terms as "anger," "aggression," and "hostility." The DSM is no exception with its definition of irritability as persistent anger, a tendency to respond to events with anger outbursts or blaming others, and an exaggerated sense of frustration over minor matters. The definition concern emphasizes the need to consider irritability in terms of its emotional, behavioral, physiological, and cognitive aspects.

Physical Illness and Irritability

There are four different pathways that link irritability with physical illness.

First, irritability can be induced by a physical illness. This is the case in serious acute illnesses, which interrupt an individual's daily life and cause major inconveniences like incapacity, dependency, and personal losses. Similarly, experience of a chronic illness induces a variety of unique affective responses and is associated with irreversibility and potential disability. Irritability can also represent a psychological response to disability,

hospitalization, or a medical or diagnostic procedure. For example, prenatal diagnostic procedures like ultrasound examination and amniocentesis significantly increase irritability. Additionally, irritability, like other forms of negative affect, can be involved in the development of a physical illness. For instance, hostility is related to an increased risk of cardiovascular diseases, like arthrosclerosis and coronary heart disease, while high levels of irritability influence organic gastrointestinal disorders and functional gastrointestinal disorders. Irritability is also a significant predictor of unhealthy behaviors like excessive alcohol consumption and smoking. Last, irritability is a characteristic of many physical illnesses, including Cushing's syndrome, an endocrine disease. It is also present in individuals with eating disorders and various types of skin disease.

Mental Disorders and Irritability

Irritability is a mood dimension that cuts across psychopathology and spans the internalizing and externalizing divide. Commonly referred to as mood, irritability is present in the DSM and the World Health Organization's (WHO) International Classification of Diseases (ICD-10) 10 criteria of bipolar disorder. Irritability is present in criteria for major depressive disorders in both the depressive and manic phases, as well as cyclothymia and dysthymia in children. The only formal modification of adult criteria for children is recognition by the DSM-IV that irritability is a significant feature of child and adolescent depression and an expression of distress. In general, specific criteria for major depression of adults are similar in clinic-referred child and adolescent samples, but irritability may be substituted for depressed mood. Moreover, irritability is present in a range of anxiety disorders. While it is considered a mood symptom, it is also a main constituent of temper outbursts characteristic in oppositional defiant disorder (ODD), a disruptive disorder. Irritability is also associated with obsessive–compulsive disorder, schizophrenic disorders, personality disorders, and organic mental disorders like temporal lobe epilepsy. It is also a characteristic of alcohol intoxication and withdrawal.

Treatment of Irritability

An important field of research is concerned with the treatment of chronically high levels of irritability that are associated with physical illnesses and mental disorders. Treatment methods are categorized as behavioral, pharmacological, and psychotherapeutic. Behavioral treatments include but are not limited to breathing-relaxation techniques and educational sessions on dealing with anger and hostility. Such methods have been found to be effective in reducing vital exhaustion and risk of coronary events in individuals with percutaneous coronary angioplasty. Other studies have described the effectiveness of Rational Emotive Behavior Therapy (REBT) in modifying specific irrational beliefs in children and adolescents to decrease aggression. Research is ongoing to examine whether the reduction of irritability may contribute to decreases in other physical illnesses.

In the case of mental disorders, pharmacological treatments, including the use of antidepressant drugs with tranquilizing actions for mood disorders, are far-reaching in the

prevention and treatment of irritability episodes associated with physical and mental disorders, including personality disorders. Pharmacological methods of correcting hormonal imbalances also result in significant reductions in irritability. Such a conclusion stems from research on individuals with Cushing's syndrome and hyperprolactinemia.

Psychotherapy is also used to modify abnormal levels of irritability and hostility. Although such methods require considerable clinical skill, therapeutic programs that are based on cognitive-behavioral intervention principles have been found to be effective.

Closing Statements

Mood is an essential psychological component that underlies individual differences and behavior. Mood states can be predicted by stable personality dimensions, including neuroticism and extraversion, but are often independent and, instead, are influenced by situational variables. Similarity, irritability is a dimension of mood that is present in individuals' daily lives and expressed in a variety of physical and mental illnesses. Although most research on irritability has focused on its relationships to other psychopathology, correct understanding of its characteristics and causes, and those of other mood states, is necessary for healthy quality of life and health problem intervention and prevention.

Judgments of Personality

Emily R. Bunnett

Swinburne University of Technology, Hawthorn, Vic, Australia

Personality research across disciplines and uses, including questionnaire development, has largely centered on the development of a sufficient taxonomy of traits. Through multivariate methods, mostly factor analyses, of all trait descriptors and adjectives employed in natural language and personality questionnaires, a consensus has arisen as to the number of core factors underlying personality. A total of five factors is said to best represent the factor structure of personality and provide a comprehensive overview of one's temperament (Weisberg et al., 2011). The five factor model or Big Five comprises Extraversion, Agreeableness, Conscientiousness, Openness to Experience, and Neuroticism; however, the exact number and makeup of the facets underlying each broad factor require further deliberation and may vary according to the context and purpose of testing. Nevertheless, while a large number of personality inventories provide an indication of participants' standing on these Big Five factors, there are a variety of test types and hence outcome measures, with the exact format of the measure and results presented varying according to the model on which it was developed and the intended use of the results obtained. The focus of this entry will be on outlining the different types and methods of personality testing and assessment and providing examples of each, whilst comparing the various outcomes provided and the contexts in which they are most commonly used.

Personality Testing and Assessment

A personality test is a standardized instrument, inventory or questionnaire that is developed to reveal aspects of character or temperament. Personality tests were first developed to aid the process of personnel selection and are still commonly used for this purpose and/or in research into individual differences. In comparison, personality assessment is often used in diagnosing psychological disorders and incorporates a variety of personality measures, including

interviews and a battery of projective, objective, and situational tests. The most common types of personality tests are projective and objective. Specifically, projective measures of personality are founded on psychoanalytic theories and hence employ ambiguous stimuli to signal aspects of underlying personality traits.

In comparison, objective tests, such as self-report measures, comprise a restricted response format (ordinal rating scales or true/false responses), rely on an individual's personal response and are relatively free of response biases (i.e. contain extensively tested validity scales). The most common objective personality test is the Minnesota Multiphasic Personality Inventory (MMPI; Hathaway & McKinley, 1951). Personality inventories, lexical tests, and questionnaires are all examples of objective tests. Personality inventories are self-report questionnaires on which participants provide reports on their own feelings and behaviors and that commonly employ a true/false or yes/no response format (Feingold, 1994). The lexical method proposes that a comprehensive review of personality can be achieved through assessing individual differences in response to single-term adjectives of underlying traits. Lexical inventories are also often presented as bipolar scales, on which a participant is to rate where they stand between the two polar opposites of a single dimension. Conversely, personality questionnaires provide participants with behaviors or statements that provide insight into the underlying traits and are asked to rate the degree to which they agree with the statement. Questionnaires may provide better criterion-related validity as the items provide participants with a frame of reference and hence enable them to better compare the degree to which their behavior in the past is in agreement with the statement. Similarly, lexical tests may be more open to response biases as they are generally more transparent. Nevertheless, the degree to which one displays response biases, such as impression management and self-deception, may be more reflective of the purpose for undertaking testing. For example, Cellar, Miller, and Doverspike (1996) found that a six-factor structure provided a better representation of data collected using a bipolar lexical inventory for employee recruitment, although, the factor structure was incomprehensible and poorly defined, likely reflecting participants' attempts to respond in a socially desirable manner.

Table 1 *Various Personality Tests Used Overtime and Currently*

Test	Author & Year	Description
Activity Vector Analysis	Clarke and Associates, Inc. (1956)	Self-report questionnaire used to measure aggressiveness, sociability, social adaptability, and emotional control. Used for recruitment
Bem Sex-Role Inventory	Bem (1974)	A 7-point Likert measure of 20 masculine, 20 feminine and 20 filler traits aimed at assessing masculinity, femininity, and sex roles
California Psychological Inventory	Gough (1956)	Self-report inventory with 434 true/false, non-clinical, everyday behaviors and traits
Eysenck Personality Questionnaire	Eysenck and Eysenck (1985)	Questionnaire that provides a measure of extraversion, neuroticism, and psychoticism
Hare Psychopathy Checklist	Hare (1980)	A 20-item checklist that is to be completed on the basis of a semi-structured interview to assess perceived personality traits and observed behaviors
RIASEC	Holland et al. (1969)	A measure and theory that matches personalities and careers, and results in a classification of being Realistic (Doers), Investigative (Thinkers), Artistic (Creators), Social (Helpers), Enterprising (Persuaders), and Conventional (Organizers)
Keirsey Temperament Sorter	Keirsey	A self-report personality questionnaire that helps people better understand themselves and others. The measures presents items with two alternative response options. People are subsequently categorized as guardians, rationals, idealists, or artisans
Minnesota Multiphasic Personality Inventory	Hathaway and McKinley (1951)	A standardized objective measure of personality and psychopathology that is most commonly employed for clinical diagnoses, treatment planning and assessment and personnel recruitment/employment
Millon Clinical Multiaxial Inventory	Millon, Grossman, and Millon (1969)	A standardized measure of psychopathology (including specific psychiatric disorders outlined in the Diagnostic and Statistical Manual of Mental Disorders) and personality traits
Myers-Briggs Type Indicator	Briggs and Myers (1929)	An introspective, self-report measure of personality type, that indicates your preference on four dimensions: (1) where you focus your attention (Extraversion or Introversion), (2) the way you take in information (Sensing or Intuition), (3) how you make decisions (Thinking or Feeling), and (4) how you deal with the world (Judging or Perceiving)
Pearson-Marr Archetype Indicator	Pearson and Marr (2002)	A 5-point Likert type scale that provides an index of the presence of 12 archetypes at that point in time
Rorschach Inkblot Test	Rorschach (1921)	Projective personality measure, wherein participants are asked to describe what they see in a series of ambiguous inkblots. Their verbal descriptions are subsequently interpreted as revealing aspects of their inner personality

(Continued)

Table 1 (Continued)

Test	Author & Year	Description
The Sixteen Personality Factor Questionnaire	Cattell (1949)	A self-report, lexical inventory that assesses 16 major factors of personality, as identified following decades of factor analytical research
Taylor-Johnson Temperament Analysis	Johnson (1941)	A bipolar, lexical personality inventory designed to assess nine personality traits that relate to individual adjustment
Temperament and Character Inventory	Cloninger and colleagues (1993)	A personality measure that assesses four temperaments (novelty seeking, harm avoidance, reward dependence and persistence), and three characters (self-directedness, co-operativeness and self-transcendence)
Thematic Apperception Test	Murray (1943)	A projective psychological test, wherein participants provide narratives to a series of ambiguous pictures of people, which are subsequently interpreted as revealing underlying aspects of personality
DISC	Marston (1928)	A behavior assessment tool that may be used for personnel selection and recruitment through providing insight into four personality domains: dominance, inducement, submission and compliance
The Hand Test	Wagner (1962)	A projective technique that employs ten unbound 3.5×4.5 in. cards, nine with simple line drawings of single hands, and one blank card, to measure how the viewer interprets what each hand is doing. The blank card is left open to the imagination of the participant. Participants provide verbal responses which are recorded, scored and interpreted by the administrator
HEXACO	Ashton, Vries and Lee (2017)	This six-dimensional model of personality was formulated on the basis of several previous lexical studies and factor analyses of trait adjectives. Self-report or observer ratings are employed to provide an indication of one's standing on the following six personality dimensions: honesty/humility, emotionality, extraversion, agreeableness, conscientiousness and openness to experience
International Personality Item Pool (IPIP)	Oregon Research Institute	The IPIP is a freely available list of items for use in personality tests
Newcastle Personality Assessor	Nettle (2007)	A measure of the Big Five personality factors
Swedish Universities Scales of Personality	Gustavsson et al. (2000)	A personality measure of 13 personality traits: somatic trait anxiety, psychic trait anxiety, stress susceptibility, lack of assertiveness, impulsiveness, adventure seeking, detachment, social desirability, embitterment, trait irritability, mistrust, verbal trait aggression and physical trait aggression

Table 1 (Continued)

Test	Author & Year	Description
The Birkman Method	Birkman et al. (2008)	An online measure of social perception, personality and occupational interest assessment consisting of 10 scales describing occupational preferences (Interests), 11 scales describing "effective behaviors" (Usual behaviors), 11 scales describing interpersonal and environmental expectations (Needs or Expectations), and 11 scales that describe "less than effective" behaviors (Stress behaviors)
True Colors Personality Test	Lowry (1978)	A personality profiling system similar to the Myers-Briggs personality inventory described above. It was originally developed to categorize four basic learning styles or personality types using the colors blue, orange, gold, and green to identify the strengths and challenges of each. Everyone's personality consists of a combination of all four colors. Nevertheless, the two dominant colors are said to best reflect the individual's core temperament; green personality types are independent thinkers, gold are pragmatic planners, orange are very action-oriented, and blue are very people-oriented
Woodworth Personnel Data Sheet	Woodworth, developed during WWI	The Woodworth Personnel Data Sheet is commonly referred to as the first personality test, being developed during WWI to screen recruits for susceptibility to shell shock; however, it was not completed on time for utilization during WWI and was instead employed in much subsequent research
The Revised NEO Personality Inventory	Costa and McCrae (2008)	A 240-item 5-point Likert scale personality questionnaire that assesses participant's standing on the Big Five personality factors. A 60-item short version of the questionnaire is also available. Form S provides a self-report measure, while Form R is designed for observer ratings. All of the Big Five factors of personality are embody six more specific facets

Learned Helplessness

Harriet Winterflood and Emma A. Climie

Werklund School of Education, University of Calgary

Learned helplessness is a behavioral response that occurs when individuals realize that the outcomes following a response are uncontrollable. For example, a child who is struggling with mathematics and continually performs poorly on tests and assignments may quickly begin to feel as though nothing he does may improve his performance and when he subsequently encounters math-related work, he may experience a sense of helplessness. As adults, individuals continue to encounter situations where they demonstrate learned helplessness behavior. For example, those who were once engaged with the political process may become frustrated with lack of change or perceived broken promises. As a result, individuals may become discouraged and no longer exercise their right to vote, as they believe that their voice does not matter.

Learned helplessness is a result of individuals being exposed to negative consequences (e.g., failing a math test), independent of one's behavior (e.g., trying very hard) and continues to impact the individual's future behaviors (e.g., no longer willing to try to improve math abilities). Learned helplessness only occurs if the individual has no control over the aversive event, and does not occur if the individual does have some control over the outcome. There are three primary components of learned helplessness: motivational, emotional, and cognitive.

Motivational

Individuals that demonstrate learned helplessness exhibit a decreased motivation to respond to a behavior due to their previous experiences. Specifically, individuals may be unmotivated to respond as they believe that the same outcome will occur, regardless of their behavior. Individuals who believe that they have no control over the outcome become helpless more easily than individuals who believe they have control over the outcome.

Emotional

Individuals with learned helplessness exhibit changes in emotionality. Individuals are often more emotional when uncontrollable events first occur. Initially, they often exhibit an increased emotional response to an outcome; this emotion is often identified as fear. Once the individual learns that the outcome is uncontrollable, the fear decreases, and feelings of depression begin. For example, a child who has failed an exam may be fearful of failing his or her next exam. However, once the child learns that he or she has no control of whether or not he or she passes the exam (i.e. the same result occurs regardless of whether the child studies or not), the feelings of fear decrease, and the student now begins to exhibit depressive feelings. In sum, individuals with learned helplessness may initially demonstrate a heightened emotional response to an outcome; if they are repeatedly exposed to the same outcome, they may then begin to display a decreased emotional response.

Cognitions

Individuals often have difficulty believing that their behavior has been successful. Individuals with learned helplessness often have difficulty recognizing their action and the consequence as dependent; instead, consequences are perceived as independent of one's actions and behaviors. For example, consider an individual who failed their first three driving tests, but passed the fourth time. If this individual demonstrates learned helplessness, he or she may believe that he or she passed the fourth time due to luck, instead of believing that his or her hard work and effort resulted in passing the test.

Connections to Psychological Disorders

Learned helplessness negatively impacts behavior and physical functioning and may lead to the development of psychological disorders. Learned helplessness may also exacerbate the negative symptoms of many psychological disorders. Specifically, learned helplessness is thought to be a primary process in the development of depression, as well as being associated with anxiety, shyness, posttraumatic stress disorder (PTSD), and schizophrenia.

Depression

Depression is a mental health disorder, characterized by persistent feelings of sadness and loss of interest in enjoyable activities. Learned helplessness is a central model of depression. Specifically, individuals that experience learned helplessness often focus primarily on negative experiences (i.e. conceding a goal in soccer) rather than positive experiences (i.e. scoring a goal in soccer). As a result, individuals begin to demonstrate depressive symptoms, such as a lack of positive emotions and pleasurable feelings in response to activities that were once enjoyable.

Anxiety

Anxiety disorders are characterized by constant, debilitating feelings of worry and fear. It is common for individuals that are exposed to uncontrollable aversive events to display increased fear and/or anxious behaviors, such as increased social avoidance. Thus, learned

helplessness can exacerbate the symptoms of anxiety. Additionally, learned helplessness may help account for an individual's anxiety-related symptoms (i.e. increased fear of a specific item, event, or situation).

Posttraumatic Stress Disorder

PTSD is a trauma- and stressor-related disorder that occurs when an individual has experienced or witnessed a traumatic event, such as a natural disaster, death, or war. It causes significant distress or impairment in one's social interactions and daily functioning. PTSD and learned helplessness both exhibit similar symptoms. Specifically, one major characteristic of PTSD is re-experiencing the precipitating event; individuals with learned helplessness may also re-experience previous, traumatic events. Further, occurrence of PTSD in individuals that have been victims of domestic violence may be specifically associated with high levels of learned helplessness. Thus, individuals with learned helplessness may be at an increased risk of experiencing PTSD.

Shyness

Learned helplessness may also exacerbate an individual's shyness. For example, an individual who feels shy in certain situations may begin to feel that he or she has no control of his or her feelings; in turn, he or she may believe that it is unable to overcome these feelings. The feelings of a lack of control may result in the individual avoiding these situations, in turn, worsening the shyness.

Schizophrenia

Schizophrenia is a neuropsychiatric disorder characterized by hallucinations, delusions, and disorganized speech and behavior. Individuals with schizophrenia often have difficulty performing tasks and frequently exhibit learned helplessness behaviors. Specifically, they may hold negative beliefs about their ability to succeed at a task, which negatively effects their motivation and effort. Thus, many individuals with schizophrenia give up and stop trying; this behavior may, in part, be due to their exposure to previous uncontrollable experiences (i.e. negative criticism).

Implications

Learned helplessness can negatively impact on behavior and physical functioning. Learned helplessness can impact children, youth, and adults in a number of ways throughout their lifetime. In particular, learned helplessness may have an impact on academic success/motivation, physical health, mental health, and social well-being.

Academic Success/Motivation

Learned helplessness is often directly related to a student's academic success and motivation. Students who demonstrated learned helplessness behaviors are often unwilling to engage in academic tasks because they believe that, regardless of their effort, they will not

be successful. For example, students with learned helplessness may refuse to complete a homework task or study for a test, as they may believe that regardless of whether they study or not, they will still do poorly on the exam. Overall, students with learned helplessness often believe that they have no control over the outcome, and that regardless of their actions or behavior, the end result will be the same.

Students with learned helplessness tend to blame themselves for failure. Specifically, individuals will often believe that failure occurs due to personal characteristics or abilities (i.e. they believe they are poor spellers, regardless of ability). Additionally, it is often believed that the reasons for failure are unchangeable and uncontrollable. Further, students with learned helplessness do not take credit for success. In cases where one succeeds, the success is justified in terms of environmental factors (i.e. the exam was easy). Students with learned helplessness frequently present with feelings of hopelessness and incompetence.

Physical Health

Learned helplessness can also impact physical health. Learned helplessness is often generalized across similar situations; thus, individuals that experience learned helplessness in academia may often generalize learned helplessness to sports or other physical activities. An individual that consistently struggles in sports and physical activity may feel inadequate and become unwilling to participate in future physical activities. For example, an individual that consistently fails to hit a hockey puck may believe that he or she is unable to play hockey and is therefore bad at all sports. This lack of confidence in his or her performance may prevent him or her from participating in sports in the future. This belief often results in the individual avoiding physical activity, and becoming sedentary, which may lead to other negative health effects.

Social Impact

Many victims of domestic violence experience learned helplessness. It is unclear whether domestic violence results in learned helplessness, or whether an individual experiences learned helplessness due to his or her life experiences; however, when looking at the link between abuse and mental disorders (specifically PTSD and depression), learned helplessness is often an influential factor. In particular, learned helplessness contributes to a victim's obedience and passivity as well as reluctance to leave an abusive relationship. Overall, learned helplessness is commonly experienced in victims of domestic violence and it can increase the negative impact of abuse on an individual's overall mental health.

Mental Health

As previously discussed, learned helplessness is associated with a number of mental disorders, including depression, anxiety, and PTSD. Learned helplessness is a primary model of depression, and can be used to explain symptoms of many psychological disorders. Additionally, learned helplessness may influence the severity of symptoms in individuals with psychological disorders (i.e. social avoidance in individuals with anxiety).

Overcoming Learned Helplessness

A number of different methods can be used to help individuals overcome learned helplessness. These strategies include pharmacological treatments and the use of cognitive therapy strategies.

Pharmacological Treatments

Medications can be utilized to help overcome the effects of learned helplessness. Uncontrollable stress can lead to changes in neurotransmitter levels, specifically, increased activation of serotonin and reduction of norepinephrine; these neurochemical changes can lead to behavioral symptoms of learned helplessness. Owing to the neurocognitive component of learned helplessness, anti-depressant medication may help to reduce the symptoms of learned helplessness. Often, anti-depressants that target serotonin and/or norepinephrine levels are used (e.g., Prozac). Not all individuals require pharmacological treatments to overcome learned helplessness, as the use of cognitive strategies has also been found to be effective.

Cognitive Therapy

Individuals with learned helplessness believe that the outcomes following a response are uncontrollable. To overcome learned helplessness, the individual must learn to change the way that they think, moving from feelings of helplessness to feelings of control. Cognitive therapy is one method that can be used to help people replace helpless thoughts with more positive thoughts, referred to as learned optimism. There are several cognitive therapy strategies that can be used. First, individuals can be encouraged to identify when they are interpreting events negatively. Additionally, individuals may be encouraged to generate more accurate interpretations of events. Finally, individuals may be encouraged to think about different consequences for an event, rather than the worst possible consequence.

Individuals with learned helplessness may also have difficulty with problem-solving skills and social skills. Cognitive therapy strategies can be used to help develop problem solving skills and social skills, which, in turn, may help individuals to overcome learned helplessness. Additionally, parents of children with learned helplessness can help by providing opportunities for children to be in control; for example, children may be allowed to choose what to eat for dinner, what clothes to wear, and in what activities they would like to participate.

Life Satisfaction

Irene López-Gómez[1], Covadonga Chaves[2], and Carmelo Vázquez[2]

[1] *Rey Juan Carlos University*
[2] *Complutense University of Madrid*

Concept

Life satisfaction (LS) is defined as the judgment of one's own life. Asking about LS may activate a global complex judgment that comprises comparing aspects of life to ideal standards, social comparison, aspirations and goals, one's past circumstances, and one's needs. The time frame can be referred to life "since birth" or to a specific moment in time. Likewise, LS is a term used globally (about one's life in general), but also can make reference to specific domains, such as health, education, family, social relationships, work, housing, or leisure. Interestingly, although global LS and domain satisfaction are substantially related, significant discrepancies can arise.

Following Ed Diener's influential conceptualization of subjective well-being (SWB), LS is often considered as the cognitive component of SWB whereas the reported affective state would be its emotional component. Although both components of SWB are correlated, the relative importance of each component may vary depending on the cultural setting (e.g. people in individualistic societies give more importance to pleasure and enjoyment whereas people in collectivistic societies give more prominence to life satisfaction or meaning in life even at the expense of the emotional well-being). Variables such as age, personality, values and life goals can also affect the relative weight of each SWB component.

Demographic, Structural Factors and LS

Although LS is relatively stable within individuals, it is also a sensitive index that varies across nations and cultures, as well as across economic and demographic variables (e.g. gender, age, education). The World Happiness Report (Helliwell, Layard, & Sachs, 2012, 2013) has found that, when comparing LS measures in different nations, more than three quarters of cross-country differences in average can be explained by variables already

known through experimental and other evidence to be important (GDP per capita, years of healthy life expectancy, inequality, social support, perceptions of corruption, prevalence of generosity, and freedom to make life choices).

Age

Age does affect LS scores in different ways depending upon the social and economic context. Whereas psychological well-being is highest at the youngest and oldest ages (a U-shaped relationship) in high-income English-speaking countries, in other regions (like Latin America or Eastern Europe) there is a continuous decline with age although the causes of these variations are not well known yet (Steptoe, Deaton, & Stone, 2014).

Gender

Evidence from different studies suggests that women have slightly, but significantly, higher average levels of evaluative well-being (measured by LS scales) than men worldwide. Interestingly, this positivity may be paradoxical when higher rates of depression are observed in women than in men worldwide.

Employment

Compared to their employed counterparts, unemployed people have been found to have lower measured LS and domain satisfaction, worse psychological health, and lower overall happiness. Many studies have revealed that the reduction in well-being caused by unemployment is larger than the reduction attributable to the loss in income – in other words, there is a larger effect on well-being from losing social status, workplace social life, self-esteem, and other factors, than the effect of losing income.

Personality

Among individual factors, personality traits are associated to LS at every age. It has been found that extraversion, neuroticism, agreeableness, and conscientiousness are associated to LS scores. Other factors, such as self-satisfaction (which is an important predictor of overall satisfaction) or interpersonal relationships, community involvement, and development of significant activities, are important LS pillars throughout life.

Health

Good health (measured as self-rated health and also in terms of the objective presence or absence of a disease or disability) is associated to higher well-being. This seems instinctive – people who are healthier, all else being equal, will probably be happier, although the impact of health problems on well-being may depend on the nature of the disorder. For instance, national surveys have shown that mental health problems have a much larger effect on LS than physical illnesses (Steptoe et al., 2014). What is even more interesting, there is a large body of experimental and longitudinal evidence showing that well-being causally influences both health and longevity and positive SWB is a protective factor for

health. In fact, well-being has been associated with improved cardiovascular health, immune functioning, reproductive health, less pain and greater pain tolerance.

Life Events

One of the factors that can affect LS is the perception of changes in life circumstances although, in the majority of cases, after a time LS returns to previous levels due to an adaptation process. Nonetheless, there are highly stressful or traumatic events that can affect well-being in the long term.

Measures of LS

In the last decade, there have been several calls to measure well-being from high-profile scholars and organizations. For example, in 2009 the Commission on the Measurement of Economic Performance and Social Progress, led by Nobel Prize-winners Joseph Stiglitz and Amartya Sen, called for better measures of societal progress, and their comments garnered to huge international attention. Detailed questions on SWB have been included in high quality social surveys, for example in some recent waves of the European Social Survey (ESS) and the European Quality of Life Survey (EQLS). In 2011, the Organization for Economic Development (OECD) launched its Better Life Initiative (www.oecdbetterlifeindex.org) at the center of which is its Better Life Index, a multidimensional measure of progress and well-being (see Table 1); and since 2012 the World Happiness Report has been published annually.

Several measures of LS have been developed that consist of asking respondents to evaluate either their lives as a whole or each life domain (typically on a scale ranging from *very satisfying* to *very dissatisfying*) (Table 1). There is ample evidence, accumulated over years of sound research, on the consistency and validity of these subjective assessments.

Reliability of LS Measures

High correlations between life evaluation scores from different measures and between a measure given repeatedly across short time intervals indicate the high reliability of LS measures.

Although measures of LS are relatively stable, they are not insensitive to changes in life circumstances. About 60–80% of the variability in repeatedly assessed LS scales is associated with long-term factors (e.g. childbirth, changes in marital status or in income). The remaining 20–40% is due to occasion-specific factors and error of measurement (Eid & Diener, 2004).

Validity of LS Measures

LS has shown clear discriminant validity from related concepts such as positive affect, negative affect, optimism, and self-esteem. Concerning inter-rater validity, Schneider and Schimmack (2009) meta-analyzed 44 studies and found a mean correlation of 0.42 between self-reports and the reports of the participants' LS from other informants (e.g. family or friends), which was higher than the comparable figure for reports on moods and emotions of the participants.

Table 1 *Measures of Life Satisfaction*

Measure	Author (year)	Description
Cantrill's Ladder Scale	Cantrill (1965)	1-item scale where responders are asked to place themselves on an imagined ladder with steps numbered from zero at the bottom (*the worst possible life*) to 10 at the top (*the best possible life*).
Satisfaction with Life Scale (SWLS)	Pavot and Diener (1993)	5-item scale which results in a total score. It is the most commonly used scale to assess LS.
Australian Personal Well-Being Index (PWI)	International Wellbeing Group (2006)	8 items to assess satisfaction with 8 different areas (living standards, health, accomplishments, relationships, safety, community, future security and religiosity/spirituality) and an item of general LS.
Your Better Life Index (BLI)	OECD (2011)	This is a tool that allows comparison of countries' performances according to 11 dimensions of well-being (housing, income, jobs, community, education, environment, civic engagement, health, Cantrill's ladder, safety, work-life balance). http://www.oecdbetterlifeindex.org
Students' Life Satisfaction Scale	Huebner (1991)	7-item measure of LS for children (ages 8–18).
Multidimensional Students' Life Satisfaction Scale (MSLSS)	Huebner (1994)	40-item scale to assess life satisfaction in five dimensions (family, friends, living environment, school, self). There is also a 5-item Brief Multidimensional Students' Life Satisfaction Scale (Luhmann et al., 2012).

Longitudinal studies reveal that LS often precedes and predicts selected outcomes. Low levels of average national LS are related to higher suicide and LS scores also significantly predict health and longevity (Diener & Chan, 2011). A study found that those people high in LS were more likely during the next five years both to get married and become parents, and were less likely to become separated, relocate, or lose their job (Luhmann et al., 2012).

There is no doubt that measuring LS, and well-being in general, is a legitimate scientific and societal goal. Along with economic and social indicators, LS provides a broader picture reflecting the quality of people's social lives. Encouraging public policies that promote psychological well-being is an area in which social scientists and policy-makers are becoming interested. Attempts to improve people's lives, transcending the usual economic parameters, are not trivial but necessary, and LS is a valuable approach in this ambitious scientific and political enterprise.

Conceptualized and Categorized

How much control do you believe you have over your behavior, your environment, or your health? Most psychological theory explains that a feeling of personal control that we believe ourselves to have is very important to us in adaptive functioning, because it helps us successfully negotiate our way through life. Many empirical studies report that people who feel that they have the means to obtain desired outcomes and to avoid undesirable ones are better able to sustain emotional stability, well-being, and a favorable life in general than people who feel that their lives are determined by forces outside themselves.

In the mid-1960s Julian Rotter first introduced the idea of locus of control (LOC) to describe the generalized expectancy that personal actions will be effective to control or master the environment within social learning theory. According to Rotter's construct, people vary on a continuum between the two extremes of "internal" (I) and "external" (E) LOC in regard to personality and individual differences. He developed the I-E Scale measure which consisted of 29 questions having two options for respondents to choose from: one option expresses a typical attitude of I-LOC expectancy, and the other option an attitude of E-LOC expectancy, in which the higher the score, the more external the individual is regarded.

"Locus" means "place," and the logic behind the use of the I-E Scale measure is that a person perceives more control when the locus of that control is "internal," thus contingent on the person's own behavior, than when the locus is "external," thus dependent on the actions of other persons, or a matter of fate, luck, or chance. The principal function of the generalized expectancy assessed by the I-E Scale measure is to aid in the prediction of behavior. The potential for a given behavior to occur in a given psychological situation is a function of the expectancy that the behavior will lead to a particular reinforcement and the value of that reinforcement to the individual in that situation.

Lefcourt (1976), a follower of Rotter's, defined internal control as the perception that positive or negative events are related to one's own behavior and thus are under personal control. An individual with high I-LOC believes that his or her own actions caused the outcome. High I-LOC people experience themselves as having personal control over themselves and events; they do things. Conversely, external control is defined as the perception that positive or negative events are unrelated to one's own behavior and thus are beyond personal control. An individual with high E-LOC believes that the outcome was determined by outside forces. These people view most events as dependent on chance or controlled by powers beyond human reach.

Wallston, Wallston, & DeVellis (1978) expanded Rotter's original scale beyond the simple I-E dimension to develop the multidimensional health locus of control (MHLC) scale, which measures the effect of beliefs on health outcomes in health-care specific settings. The MHLC consists of three dimensions: internality – the belief that health status is controlled by one's actions; chance – the belief that chance is affecting the outcome of health; powerful others – the belief that powerful other people control one's health.

Similarities of LOC to Other Constructs

There is an affinity between LOC and other psychological theories and constructs such as attribution theory, controllability and coping in regard with learned helplessness, optimism/pessimism, and self-efficacy. Attribution theory has been one of the most influential topics on LOC studies. Heider (1958) introduced this theory to psychology and classified the reasoning styles for behavior and events into two groups: internal attribution and external attribution. Internal attribution induces consciousness of self-responsibility for the given behavior and its outcomes, whereas environmental and situational factors are listed when one made external attribution.

Weiner (1992) suggested that outcomes from initial intrinsically/extrinsically motivated behavior would affect present motivation for future behaviors, and constructed three categories of attribution as applied to achievement motivation: LOC (internality-externality), stability (stable-unstable), and controllability (controllable-uncontrollable). LOC influences perseverance on one's commission. Stability is related to one's expectation for future outcomes. Controllability affects one's belief system for appraisals of surroundings. Beyond this three-dimensional model, Seligman added a global-specific category.

Bandura (1977) revealed that self-efficacy affects the choice of present behavior via expectancy of required exertion and one's idea about controllability. His concept differs from LOC because it was belief within a particular behavior and situation, though Bandura's followers expand his idea as generalized self-efficacy on relating behaviors and similar situations with the initial self-efficacy.

Maier and Seligman (1976) applied another related concept of learned helplessness to human motivational and coping styles and psychopathologies based on their classical conditioning experiments using dogs. They argued that people tended to abandon their own control on their situations when experiencing repeated negative outcomes from their behaviors. And those who attributed these situations with I-LOC, as stable and global, would have deep negative moods and no control over their all present surroundings, and fall into clinical

depression or other mental illnesses. Seligman developed his idea relating to optimism and further as positive psychology. Optimists generally attribute successful situations with the internal, stable, and global, and unsuccessful situations with the external, unstable, and specific. This explanatory style in optimists is the so-called "self-serving bias" (Bradley, 1978).

Dispositional optimism was defined in terms of generalized outcome expectancies by Scheier and Carver (1985). The concept of optimism also includes explanatory style of behavior and events, and involves cognitive, emotional, and motivational components. While a pessimistic explanatory style improves one's abilities and stress coping skills, a more optimistic outlook on life helps individuals to cope and challenge the self-defeating attitudes more effectively. Is explanatory style a stable characteristic over the life stage? An explanatory style for negative life events among elderly people showed significant stability over five decades. Peterson et al. (1988) suggested pessimistic explanatory style at age 25 predicted the increase of self-reported illness between the ages of 40 and 60.

In past decades, it was believed that accurate perception of reality was the best way to have a healthy mind; however, more recent findings suggested the power of positive self-illusion. Healthy and happy people often have erroneous strong beliefs in I-LOC for successful events and of themselves such as their ability to control the world, recently described as "mind-set." Dweck (2007) introduced two fundamental categories of mind-set: growth mind-set and fixed mind-set. She formulated these categories based on her primary researches about motivation, personality, education, and development.

Like the concepts of LOC and attribution styles, mind-set consists of beliefs and/or expectations including one's implicit views of where abilities come from. People with growth mind-set can accept their own I-LOC, pliable thoughts and feelings, and dedication and effort. Hence, this mind-set will give rise to success or personal improvement even if they are not satisfied with the outcomes of their behavior. Conversely, individuals with fixed mind-set tend to be convinced that facets of themselves and the environment surrounding them are permanent and cannot be changed meaningfully.

Application and Contribution of LOC Researches

Positive psychology is very much concerned with personality and individual differences of a sense of personal control. It is well-known that LOC is the trait most strongly implicated in resilience to stress and health, as well as motivation. The transactional model developed by Lazarus and Folkman (1984) suggests LOC is a moderator of stress-coping processes and stress responses leading to ill health.

Many researchers on chronic disease in behavioral medicine have suggested that internal health LOC belief has a positive effect on self-management behavior and motivation of rehabilitation in patients with diabetes mellitus, obesity, or hyper-cortical dysfunction. Another area of applied research that has investigated LOC is psychiatric medicine. Precipitate mechanism of depression could be related to E-LOC belief about the world and the future. Cognitive-behavioral therapy proposed that cognitive restructuring which focuses on low self-controllability for stressful life events was useful for depressive patients.

Attribution therapy of LOC is useful not only for depression but also for learned helplessness in children with developmental disabilities. Resilient people have flexible cognitive

mechanisms that help them deal with demanding life events and balance in life. Highly resilient people show energetic, active, curious and resourceful personality traits, while brittle and over-controllable people show inhibited, constricted, worrying and anxious personality traits and withdrawal behavior under stress.

However, excessive effort of self-control and rumination of negative thought is more likely to lead to relapse of depression. So, intervention and relapse prevention of depression by mindfulness-based cognitive therapy and stress-management training are intended to adjust excessive thought control. Health psychology regards a new concept called "bi-local expectancy" (April et al., 2012), a mix of I-LOC and E-LOC, as a flexible coping style for individual happiness and optimal well-being.

Further studies which incorporate the standardized criteria for classifying individuals as internals or externals using the standardized LOC construct with cut-off scores across the cultural context should produce solid results, and have considerable value in understanding behavior-based LOC.

Loneliness

Conceptualized and Categorized

Loneliness is defined as a negative emotional state that occurs when an individual feels that his/her social relationships are not what he/she wants, in terms of quality or quantity (Peplau & Perlman, 1982). For most people, loneliness is a transient experience because it is influenced by changes in circumstances (i.e. moving away from home) that people adapt to. However, some people experience prolonged loneliness, which is a painful experience that has detrimental mental and physical health outcomes (Hawkley & Capitanio, 2015).

The most prominent theory of loneliness is the evolutionary theory of loneliness (Cacioppo & Hawkley, 2009). Cacioppo and Hawkley posited that loneliness is the social equivalent of physical pain, hunger, and thirst; the pain of social disconnection motivates the maintenance and development of social relationships necessary for the survival of human genes. That means feelings of loneliness generally succeed in motivating people to reconnect with others following geographic relocation or bereavement. Thus, just as physical pain is an aversive signal that evolved to motivate humans to take action to minimize damage to the physical body, within the evolutionary model of loneliness, loneliness is seen as an aversive state that evolved to motivate humans to minimize damage to the social body.

It has been argued that the protection of the social body occurs through the activation of an evolutionary mechanism known as the Re-Affiliation Motive (RAM; Qualter et al., 2015); the RAM is activated by the negative emotional state felt when lonely. Activation of the RAM increases people's attention to social stimuli to promote reconnection to others, and there is evidence from adult and child studies that lonely people show increased vigilance of social cues. Contrary to expectation, activation of the RAM also causes people to withdraw from social encounters, enabling attention to be focused on social cues, which leads to social reconnection.

But, why do some people stay lonely? There are risk factors for prolonged loneliness. Qualter et al. (2015) summarized the research thus far and noted that prolonged loneliness during childhood and adolescence appeared to have its origins in low self-worth and low trust. There are other risk factors, but these two have been shown to be particularly important because prolonged loneliness among older adults is also, consistently, related to a perceived lack of control, and low self-esteem. Other studies have shown biological and genetic underpinnings in the development of loneliness in adolescence (Goossens et al., 2015). The genes that have been found to be associated with the development of loneliness are often associated with attention processing, including sensitivity to emotional or social information, disengagement difficulties, and specific reward mechanisms in the brain. It is possible that there are genetic characteristics that interfere with the RAM that lead to prolonged loneliness: having specific genes may mean that some people are overly sensitive to emotional or social information or have problems disengaging from threat stimuli. Intervention work is beginning to focus on disruptions to the RAM that may be associated with prolonged loneliness.

Trajectories of Loneliness

There are changes in people's social experiences and expectations across development, and these changes can increase loneliness. There are specific points across development when loneliness peaks, and they appear to be during periods in development when there are changes to the social environment that are also accompanied by major physical and psychological developmental shifts. Specifically, the percentage of people feeling lonely "sometimes" or "often" is highest during adolescence when youths enter puberty and are faced with the challenge of establishing their own identity, and during old age when there is increasing frailty and decreased mobility accompanied by the loss of loved ones.

In addition to normative changes in loneliness across the lifespan, there is a small group of people who experience prolonged loneliness. In several longitudinal studies that are summarized in Qualter et al. (2015), researchers have found between 3% and 22% of people of different ages experiencing prolonged loneliness over time. In all of those studies, individuals following a trajectory of prolonged loneliness showed relatively poor mental and physical health.

Prolonged Loneliness and Poor Health Outcomes

Prolonged loneliness has been found to have deleterious effects on mental and physical health across development. Hawkley and Capitanio (2015) summarized the research so far. They noted the fact that depressive symptoms are a well-established outcome of prolonged loneliness, with the pattern being seen in people as young as 6 years of age. They also note the considerable research that shows prolonged loneliness predicts poor sleep, self-reported poor health, poor immune functioning, and poor neuroendocrine functioning in people aged 18 years and above, and early mortality in people aged 50+ years. There is little agreement about why there is a relationship between loneliness and depressive symptoms, but there is much better agreement regarding the mechanism that explains the relationship between loneliness and poor physical health.

In support of the evolutionary model of loneliness (Cacioppo & Hawkley, 2009), evidence shows that lonely people are hyper-vigilant of social threats. And, while that enables most lonely people to re-engage with others, being lonely and on high alert for too long leads to poor health through an increased activation of threat surveillance mechanisms, such as (1) the hypothalamic–pituitary–adrenal (HPA) axis and (2) the cardiovascular systems. Activation of these systems explains the relationship between loneliness and poor health.

Dysfunctions of the cardiovascular system are associated with loneliness. Lonely people display elevated peripheral resistance (i.e. resistance to blood flow) and lower cardiac output (i.e. the amount of blood pumped by the lower heart chambers in 1 minute). These dysfunctions lead to increased risk of cardiovascular disease in lonely people.

It appears that the health effects of loneliness in adulthood are the result of an interaction between loneliness and typical age-related effects on physiological systems in adulthood to old age. Given that health effects (i.e. disturbed sleep, poor subjective health, and increased frequency of childhood illnesses) are evident in children and adolescents who experience prolonged loneliness, it is important that physiological mechanisms underpinning poor health in lonely children are examined. The findings implicate the HPA axis as a functional mechanism that may be involved in the interaction between loneliness and health, but, to date, no published studies have reported on that during childhood and adolescence.

Cross-Cultural Differences in Loneliness

Even though loneliness is a universal experience, it is likely to be influenced by cultural factors, including cultural beliefs on the virtues and purposes of solitude. Cross-cultural research on loneliness, however, is not yet widespread. From research to date, there appears to be little difference in the prevalence of transient or prolonged loneliness across different cultures. There is also no consistent evidence that there are cross-cultural differences in relation to the experiences of loneliness within a country. One might expect that living in a country with a different cultural background may lead to loneliness, but research does not suggest that. There is a need to establish the cultural equivalence of the measure used, and such research is limited.

Measuring Loneliness

Several loneliness measures have been used in research. Each assesses loneliness in a different way. There are single item measures (e.g. "how often do you feel lonely?"), uni-dimensional scales (e.g. the UCLA Loneliness Scale), and multi-dimensional scales (e.g. the Social and Emotional Loneliness Scale for Adults). Some scales include the word "lonely," whereas others try to measure loneliness more indirectly and avoid using that term. Although several measures can be used with different age groups, most measures are used with a specific age category, such as children (e.g. the Children's Loneliness Scale), adolescents (e.g. the Loneliness and Aloneness Scale for Children and Adolescents), or the elderly (e.g. Rasch-Type Loneliness Scale). Having different measures for different age groups means that appropriate language can be used and suitable vignettes can be included, but they make it difficult, in longitudinal research, to monitor change and stability in loneliness. When comparing studies conducted with different age groups, it is also important to keep in mind that these studies may have used different loneliness measures.

Some researchers have argued for the use of measures that focus purely on the experience of loneliness. Most current measures include items that ask about the hypothesized causes of loneliness, such as perceptions of one's social competence (e.g. "it's easy for me to make new friends") or perceptions of whether one has friends (e.g. "I have a lot of friends"). It is important to avoid overlapping content in items between the assessment of loneliness and the assessments of potentially related variables, and there is a call to strengthen measures so they are clearly measuring loneliness and not related constructs.

Interventions for Prolonged Loneliness

There has been an increase in the understanding that loneliness is a risk factor for adverse psychological and physical health. This has meant there has been interest in interventions that might reduce prolonged loneliness. For instance, several governments have launched campaigns designed to increase awareness of the growing problems of loneliness and social isolation. In the United Kingdom, there is the Campaign to End Loneliness (http://www.campaigntoendloneliness.org/about-the-campaign); in Denmark, there is a campaign by the Crown Princess and her Mary Foundation (http://www.maryfonden.dk/en/loneliness); in Canada there is a campaign by the Canadian Seniors Council (http://www.seniorscouncil.gc.ca/eng/home.shtml), and in the United States, among others, Oprah Winfrey has launched a loneliness campaign (http://www.oprah.com/health/Just-Say-Hello-Fight-Loneliness). Such campaigns are not limited to these countries, and they all raise awareness of loneliness and attempt to stop the stigma surrounding it. But, they represent only a first step. Effective interventions are also needed.

A meta-analysis conducted in 2011 by Masi et al. suggested that interventions designed to modify maladaptive social cognition may be especially worth pursuing in relation to loneliness. This is supported by others (Qualter et al., 2015), who suggest that attention re-training and priming acceptance are also likely to be effective. However, there have been no randomized controlled studies in the field of loneliness to examine the effectiveness of such treatments at reducing loneliness.

Mindfulness

Erin J. Shumlich[1] and Joshua S. Bourdage[2]

[1] *University of Western Ontario*
[2] *University of Calgary*

Mindfulness Defined

Mindfulness can be defined as an active state of being highly aware to internal and external stimuli, including present sensations, feelings, and cognitions, in an accepting and non-judgmental way. In other words, mindfulness involves attending to oneself and one's surroundings without applying labels or emotionally engaging in these experiences. Mindfulness allows one to disengage from automatic thoughts and behaviors that include ego-involvement or preoccupation with unwanted thoughts, which may be maladaptive. This definition of mindfulness is rooted in Buddhism and is an essential component in the path to enlightenment in Buddhist practice.

Baer and colleagues in 2006 suggested that mindfulness consists of five facets: observing, describing, acting with awareness, non-judging of inner experience, and non-reactivity of inner experience. The observing facet of mindfulness involves being aware of internal and external sensations, cognitions, and emotions. Describing involves labeling these observed experiences objectively. Acting with awareness involves the process of content related to attending to internal and external experiences, including normally automatic actions (e.g. breathing). Non-judging of inner experiences is defined as being non-judgmental of internal and external experiences. Lastly, non-reactivity to inner experience involves allowing experiences, like thoughts and feelings, to come and go without engaging with them.

Research on mindfulness has increased dramatically over the last decade and suggests that mindfulness and associated techniques are beneficial for psychological well-being (e.g. stress reduction), mental health (e.g. reduction of anxiety and depression), physical health (e.g. decreased blood pressure), and may have wide-reaching positive effects in intimate relationships and in the workplace. For example, a mindfulness-based intervention in the workplace by Wolever and colleagues showed that employees' psychological distress (e.g. stress, anxiety) decreased throughout the intervention, particularly for those with low baseline mindfulness.

Mindfulness Conceptualized and Categorized

Mindfulness has been conceptualized in several ways. On the one hand, mindfulness has been nomologically defined by its relationship with well-defined constructs, such as personality, which suggests that mindfulness is a trait-based individual difference. On the other hand, mindfulness has been incorporated within therapeutic frameworks, with the notion that mindfulness is skill-based and can be enhanced. Furthermore, other researchers have conceptualized mindfulness as state-based, dependent on an individual's temporary situation or motives. In sum, mindfulness has been conceptualized in three primary ways: trait-based, skill-based (i.e. as a set of skills and techniques that can be learned), and state-based approaches.

These differing views of mindfulness suggest that individuals vary on the inherent ability in which they can employ mindfulness at any given time due to dispositional factors, and that mindfulness differs both between and within individuals. Research has supported all three perspectives: the trait-based, skill-based, and state-based theories. Although we focus on contextualizing the trait-based approach to mindfulness, a discussion of this construct would be incomplete without touching on the skill-based and state-based perspectives.

Perhaps most prominent, the skills-based conceptualization of mindfulness emphasizes that mindfulness can be learned and developed through practice, which is evidenced by the multitude of mindfulness programs available to help foster and grow mindfulness skills. Jon Kabat-Zinn popularized mindfulness in North America with his Mindfulness-Based Stress Reduction (MBSR) therapy in 1979. Since then, the notion of mindfulness has become increasingly popular in a number of psychotherapeutic approaches. For instance, mindfulness is a critical component of Dialectical Behavioral Therapy (DBT) and Acceptance and Commitment Therapy (ACT).

Mindfulness has also been considered state-based such that one can experience momentary mindfulness while the necessary attention and orientation to experience are maintained. For instance, state-dependent mindfulness has been found to vary based on day-to-day emotionality and well-being. Indeed, individuals vary in mindfulness due to intrapersonal factors such as levels of distraction, motivation, etc. In line with this perspective, research has shown that 15 minutes of mindfulness improves positive responses to neutral stimuli compared to a control group. Having the disposition to be mindful (trait-based) and being momentary mindful (state-based) both have been found to have positive effects on well-being, autonomy, and positive affect, in addition to decreasing levels of negative affect.

Mindfulness and Personality

In line with the trait-based theory of mindfulness, researchers have examined how mindfulness relates to well-established dispositional characteristics like personality traits. A meta-analysis by Tamara Giluk in 2009 synthesized findings from 32 samples in 29 studies to determine which personality traits in the Five Factor Model (FFM) of personality – neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness – relate to mindfulness. Additionally, this meta-analysis looked at the relationship between mindfulness and affect, which is broadly defined as experienced emotion or mood.

Negative affect was strongly negatively correlated with mindfulness ($p = -0.39$). In contrast, positive affect is positively correlated with mindfulness ($p = .34$). Similar to mindful individuals, those with positive affect are more likely to have high concentration, increased energy, and are more in tune with their experiences.

Of the FFM traits, neuroticism is most strongly negatively correlated with mindfulness ($p = -.45$), such that those high in neuroticism were low in mindfulness. Neurotic individuals tend to experience poorer psychological functioning, and tend to be anxious, irritable, and insecure, whereas mindful individuals are more tolerant and experience higher psychological well-being. Therefore, mindfulness may be particularly difficult for neurotic individuals, since these individuals tend to have opposing traits to those of mindful individuals. In line with this, research has shown certain facets of neuroticism (depression, self-consciousness, and angry hostility) are negatively correlated with mindfulness.

Conscientiousness is strongly positively correlated with mindfulness ($p = .32$). Mindful and conscientious individuals share strong self-discipline, self-regulation, and are more deliberate and thoughtful.

Extraversion, however, is weakly positively correlated with mindfulness ($p = .12$). The excitement and thrill-seeking behaviors common of extraverted individuals are not aspects of mindfulness.

Agreeableness was moderately positively correlated with mindfulness ($p = .22$). These traits share empathy, compassion, and concern for others. Additionally, agreeable individuals tend to be more trusting and believe in the good in others, which is consistent with Buddhist tradition.

Openness to experience was also found to be weakly positively correlated with mindfulness ($p = .15$). These traits share curiosity and receptivity to experience, in addition to emphasizing attention, but lack overlap in other areas.

A new concept that has been burgeoning in mindfulness literature is "social mindfulness," which has its roots in Buddhist practices. Social mindfulness incorporates and expands on general mindfulness such that it is conceptualized as an awareness of the needs and interests of others in situations of interdependence. Interestingly, the personality trait of honesty-humility (see HEXACO model) is positively related to social mindfulness ($p = .32$). Specifically, social mindfulness was related to the fairness, greed avoidance, and modesty facets of honesty-humility, indicating individuals high on these three facets tend to be higher on social mindfulness.

Similarities of Mindfulness to Other Constructs

Mindfulness has been distinguished from other socially related constructs. Although it shares variance with self-awareness, mindfulness has been shown to be a unique construct. Mindfulness emphasizes awareness and attention to current internal and external experiences. This can be distinguished from other self-referential constructs (e.g. self-consciousness, self-reflectiveness, self-awareness), which often focus on the past or future. Additionally, these constructs often involve making judgments about one's subjective experiences. Mindfulness involves an unbiased, non-judgmental observation of thoughts, whereas other self-referential constructs involve a more reflexive application of attention.

In other words, these self-referential constructs involve thinking of oneself as the result of engaging with experiences through rumination and other often maladaptive techniques. Operational definitions of these constructs have also been shown to be empirically different; mindfulness has been associated with greater well-being and adaptive emotional responses, whereas self-referential thought has been associated with maladaptive or poor psychological well-being.

Another important distinction is between everyday mindfulness and mindfulness during meditation. Everyday mindfulness is the focus in the present moment on a single stimulus, such as breathing. Mindfulness during meditation is specific to one's ability to stay focused in a mindfulness-specific activity, such as meditation. Previous research has often used these terms interchangeably. However, research has shown a lack of relationship between everyday mindfulness and mindfulness during meditation, suggesting these are different constructs. This relationship is further complicated by level of meditation experience. Mindfulness during meditation seemed to be related to everyday mindfulness for those naïve to meditation; however, this relationship did not exist for experienced meditators. This lack of relationship may point to the distinction between trait-based everyday mindfulness and state-based mindfulness in meditation.

Theories for Understanding Mindfulness

Self-Determination Theory (SDT) posits that awareness and attention are essential for control of behavior in ways that are consistent with one's values and beliefs. Mindfulness has been suggested to facilitate behavior that is consistent with one's psychological needs, like autonomy, competence, and relatedness. Mindful individuals have been shown to be less self-conscious, socially anxious, and ruminative. Mindful individuals have also been found to be more likely to act in accordance with their values and beliefs. In contrast, less mindful individuals are more likely to have reflexive, automatic responses such that the self is scrutinized, which may have maladaptive consequences. In line with this, research has shown that those high in mindfulness generally report higher life satisfaction (e.g. self-esteem, optimism, competence).

Another theory of how mindfulness facilitates well-being is Control Theory. This theory suggests that attention to and awareness of psychological, social, and physiological cues are essential to well-being. Support for this theory is shown through biofeedback research, which suggests that attention is crucial to reducing unhealthy physical ailments or illnesses. Specifically, when dysregulation occurs through reducing bodily signals (e.g. taking painkillers), attention is essential to reconnect awareness of the body's needs.

Measuring Mindfulness

Only in the last decade have scales been developed to measure mindfulness. Mindfulness measures are important to test both the efficacy of mindfulness in a clinical setting and the relationship of mindfulness with other well-known constructs (e.g. personality). The

Mindfulness and Attention Awareness Scale (MAAS) is one of the most widely used measures of mindfulness; however, critiques of this measure suggest the MAAS leaves out important aspects of mindfulness, such as non-judgmental and accepting attitude. Ruth Baer and colleagues developed two widely used measures, the *Kentucky Inventory of Mindfulness Scale* (KIMS) and the *Five Facet Mindfulness Questionnaire* (FFMQ). A more recent scale, the *Freiburg Mindfulness Inventory* (FMI), was developed in 2006 for a diverse sample. The FMI items were gathered through an extensive literature review and rated by experts.

Mindfulness measures have been found to have moderate to large positive correlations with each other. However, certain intercorrelations between test subscales are low or even negative, which may indicate that some scales are less reflective of the mindfulness construct, or that mindfulness needs to be better operationalized. At the very least, additional research on the operationalization and measurement of mindfulness would be useful.

Future Research

Given the many outcomes and critical variables associated with mindfulness, the volume of research on mindfulness is therefore not surprising; however, there are many avenues yet to explore. For instance, although it is clear that mindfulness and personality are related constructs, a more nuanced understanding of this relationship is an area for future research. Future research is needed to further explicate the nuanced relationship between mindfulness and personality traits at the facet level, as well as the independence of mindfulness beyond existing measures of personality. For example, it is unclear whether being mindful reduced neurotic tendencies or whether neuroticism impedes one from being mindful. Furthermore, although research suggests that individual differences are important in predicting mindfulness, future research could target specific psychological and social conditions that allow mindfulness to flourish.

Mindfulness research has been utilized in a wide variety of settings. For example, mindfulness has been adapted and implemented in many different evidence-based psychotherapies and is studied as an effective way to treat numerous mental disorders, including personality disorders, which have historically been treatment-resistant. Additionally, mindfulness has been a focus of workplace research, as mindfulness has been found to reduce stress and burnout and have positive effects on workplace relationships and adaptability in the workplace. Future research could further explore applicability of mindfulness in different settings.

Motivation (Achievement, Affiliation, Power)

Alex B. Siegling and Konstantinos V. Petrides

University College London

Introduction

Motivation is critical to performance and achievement, whether in education or at work. Within the confines of individual differences and measurement, motivation encompasses a wide range of constructs. Problematically, the substantive literature is relatively "fuzzy," lacking the established taxonomies and measurement models seen in other areas, such as personality and intelligence. This conceptual ambiguity is characteristic of the wider motivation literature, which is in need of a unifying general theory (Baumeister, 2016). We present a general organizational framework, including a brief overview of constructs and measurement issues. More in-depth reviews can be found elsewhere (e.g. Heggestad & Kanfer, 2000; Mayer, Faber & Xu, 2007).

Distinguishing Between Motivational Direction and Drive

The study of motivation seeks to address two fundamental questions about behavior: (1) *what* a person is motivated to do (what is the person's motivation?) and (2) *to what extent* he or she is motivated. The first question concerns the specific direction of motivation and the reasons for choosing this direction. The second question is independent of motivational direction; it concerns motivational level, typically conceptualized in terms of temporary motivational states.

To help organize and advance the area, Siegling and Petrides (2016) drew an explicit distinction between *motivators* and *drive*. The term motivators collectively refers to the various families of constructs that describe and explain a person's motivational direction, namely motives, needs, goals, interests, desires, and values. Motivators are the predominant focus of research and measurement in the motivation literature (Cattell & Kline, 1977; Mayer et al., 2007). The idea that different motivator families are similar and often used interchangeably was previously recognized by Hogan and Hogan (1996). Direct empirical

support for a unified classification of motivators comes from a relatively new measure, derived from existing measures of several of these overlapping families, specifically motives, goals, and values (Schönbrodt & Gerstenberg, 2012).

Drive, on the other hand, refers to the general level of motivation across time and situations. It differs from constructs representing a person's motivational direction, or motivators, in that it is not fundamentally tied to situations or any particular motivational area. Rather, drive is a superordinate and multi-faceted construct that manifests in various contexts (e.g. education, work, social interaction, and leisure) and subsumes interrelated motivational processes, such as planning and initiating action, sustaining effort, and enjoying these processes. For example, although drive and need for achievement (achievement motive) both implicate productive behavior and advancement, drive is not the pursuit of achievement per se but the dispositional capacity for doing things that culminate in advancement or development.

Furthermore, drive differs from specific motivational states (how much motivation a person has at any given moment) because it represents the baseline level of motivation, or the average of motivational states over time. A hypothetical illustration of the relationship between drive and motivational states over time is presented in Figure 1. In theory, a person's motivational state will be a more salient predictor of behavior in the immediate context; drive should be a better predictor of future motivational states and thereby of action in future situations. Representing a person's typical patterns in motivational affect, behavior, and cognition has some level of overlap with personality. Yet, a substantial share of drive is conceptually unique and unrelated to personality.

The difference between motivational direction and level is implicitly recognized in the study of goals. Researchers distinguish between goal content, which concerns the direction of motivation, and goal pursuit (the extent to which a person seeks to achieve goals), which is partly related to what we termed as drive. Factor analytic research confirms that motivators tend to cluster into multiple distinct dimensions (e.g. Bernard, Mills, Swenson, &
Figure 1 Drive (general motivational level) as the average of motivational states across time and situations.

Walsh, 2008; Reiss & Havercamp, 1998; Schönbrodt & Gerstenberg, 2012). In contrast, drive appears to be a superordinate and multi-faceted construct, as evidenced by measures designed specifically to assess it and measures of similar constructs.

Motivation Constructs and Measurement

Motivation constructs signify relatively stable person attributes that are typically assessed by means of questionnaires and projective measures. A few measures enquire about behavior in a specified period up to the present time (Fehnel, Bann, Hogue, Kwong, & Mahajan, 2004) or use other information, such as biodata, to infer what motives are presently driving the person (Mayer et al., 2007). Although undoubtedly related to drive or motivators, those measures primarily concern present motivational states. State motivation is a topic of special interest in industrial-organizational psychology, especially in the context of work engagement. Work engagement, which can be regarded as an outcome of motivation and other constructs, has been at the heart of the discussion of how to motivate people at work, a question also widely addressed in the popular literature by writers such as Pink (2009).

Motivators

There is an important distinction between implicit motivation (assessed using projective measures) versus explicit motivation (assessed using questionnaires and other methods), which relates to whether a given motive, goal, or value is held consciously or subconsciously. Furthermore, motivators have been categorized as approach motivation (engagement rewarded by positive outcomes) versus avoidance motivation (disengagement rewarded by avoiding negative outcomes) as well as intrinsic (from within) versus extrinsic motivation (via external incentives).

Several widely used measures assess a universal and comprehensive set of motivators (see Mayer et al., 2007), often involving combinations of the "Big Three" (McClelland, 1987): achievement (the desire to acquire new skills), affiliation (desire for social relationships), and power (desire for influencing and controlling others). Examples are the Personality Research Form, the Reiss Profile, and the Unified Motives Scales. Specific area measures assess motivators relevant to a particular context, such as work, academic, or athletic motivation.

Drive

Comprehensive measures of general motivational level also uncontaminated by motivators are difficult to find. Existing measures either integrate potential indicators of drive with motivator concepts (Liem & Martin, 2012), focus on current motivational levels (Fehnel et al., 2004), or measure related but not identical constructs with only partial overlap (e.g. grit, ambition, amotivation, goal pursuit). The Grit Scale, for instance, consists of two subscales that reflect drive (passion and perseverance), rather than any specific motivator.

Evidence from explicit measures of drive suggests that the construct comprises behavioral, cognitive, and emotional aspects beneath a superordinate construct (see also Hilgard's trilogy of mind, 1980). A hierarchical model was systematically derived from a comprehensive set of indicator traits, featuring 13 facets at the base, three aspects as the mid-layer, and the global drive construct at the apex (Siegling & Petrides, 2016). The three aspects can be labeled "effort," "passion," and "ideation."

Both versions of the measure showed adequate internal consistency and one-month test–retest coefficients of .62 (full form) or .70 (short form) (Siegling, Ng-Knight, & Petrides, 2019). Drive scores also evidenced alternate-forms reliability, cross-informant reliability, criterion validity, as well as convergent and discriminant validity (in relation to drive-like constructs and motives, respectively). Correlations with the Five Factor Model were at most moderate ($r = ..32$ to .47) and a distinct drive factor could be isolated in personality factor space. Drive scores also explained variance in well-being and work criteria over and above the NEO Personality Inventory Revised and the Hogan Personality Inventory. The concurrent and predictive effects on practical criteria (e.g. performance and achievement) remain to be investigated.

Future Directions

The distinction between drive and motivators introduces a broad organizational framework suitable for the study and measurement of motivation. Still, the different motivator families (motives, goals, interests, etc.) could be organized even better, using theoretical and empirical mapping techniques. With drive only in its infancy, the construct's nomological network will require further investigation. Following basic and eventually applied research, drive – like motivators – can meaningfully augment psychological assessments, such as in recruitment and talent management.

Neuroticism, Personality Correlates of

Kristi Chin

University of Michigan

Introduction: What is Neuroticism?

In general, neuroticism refers to the tendency to be emotionally reactive with a disposition to experience negative affect (fear, sadness, embarrassment, anger, guilt, disgust). The trait definition of neuroticism includes factors of low ego strength (maladjustment, dissatisfied emotionality), excitability, depression, inability to face emergencies, anxious sensitivity, fatigue, lack of trust, suspiciousness, guilt proneness, worry, and high frustration-tension levels. Given these defining characteristics, neurotic individuals typically show a propensity toward worry, insecurity, instability, and self-pity.

Researchers have suggested that the conceptualization of neuroticism involves more than emotional distress, and that those high in neuroticism may experience other related traits and behaviors. Negative emotions not only produce emotional distress but can interfere with adaptation and consequently, individuals who experience these negative emotions are less able to control impulses and may act on irrational ideas. Related to impulses and irrational behavior, neuroticism has been positively correlated to instances of anger and aggression (e.g. aggression due to emotional instability), but there are occasions where aggressive behavior is not related to negative emotionality (e.g. aggression due to self-defense). Further, there is a negative relationship between neuroticism and psychometric intelligence (intelligence based on psychometric testing, e.g. IQ tests), whereby intelligence increases with decreasing neuroticism. In addition, test anxiety, defined as the combination of arousal, tension, worry, and fear of failure during test situations, is strongly negatively related to neuroticism. Thus, individuals that have test anxiety may consequently experience poor test performance.

In an evolutionary sense, there appears to be a fitness advantage to neuroticism. Although too much neuroticism can impair performance, an optimal amount of this personality trait can help to defend against threats. For example, pain signals threat to physical well-being, anxiety signals social or physical threat, and depression signals to

others that help is needed. As such, individuals differ in how they respond to threatening situations, which reflects variation in neuroticism. There is consistent support for the heritability of neuroticism, where 40–60% of the variation in the trait is attributable to genetic factors, 20–30% is due to non-shared environmental influences, and close to 10% is due to shared environmental influences.

Neuroticism in Personality Models

It is agreed upon by many researchers that neuroticism is a fundamental personality trait. Neuroticism is reliably accepted as an essential domain of personality functioning and structure, and there are only a few personality models that do not include it as a dimension. For instance, neuroticism is included in Eysenck's Personality Questionnaire (EPQ-R; Eysenck, 1985) which measures three broad personality traits (extraversion-introversion, neuroticism, and psychoticism), the Neuroticism-Extraversion-Openness Inventory (NEO-PI-3; Costa & McCrae, 1976) which also includes three dimensions (neuroticism, extraversion, openness), and the Big Five personality model (also known as the Five Factor Model; McCrae & Costa, 1987) which includes five dimensions (openness, conscientiousness, extraversion, agreeableness, neuroticism). In the Big Five personality model, neuroticism is composed of facets of anxiety, hostility, depression, self-consciousness, vulnerability, and impulsiveness. Additionally, meta-analyses conducted on correlations between the Big Five and dependency found measures of dependency most highly related to neuroticism compared to the other personality dimensions. Thus, individuals higher in neuroticism tend to be higher in dependency and need greater emotional support from others. The EPQ-R and NEO-PI-3 are the more popular measures of neuroticism.

The Dark Triad is a personality model that comprises three sub-clinical personality traits – narcissism, Machiavellianism, and psychopathy. Neuroticism is not significantly correlated with narcissism or Machiavellianism, but has relationships with psychopathy. Psychopathy is characterized by impulsiveness and callousness overall, but one can further differentiate between primary and secondary psychopathy. Primary psychopathy is characterized by selfishness, lack of interpersonal affect, and remorselessness. In contrast, secondary psychopathy is characterized by an anti-social lifestyle and behaviors, as well as a lack of impulse control. There are mixed findings with regards to the relationships between neuroticism and psychopathy in research. To begin, neuroticism has been found to be positively correlated with primary and secondary psychopathy. In contrast, neuroticism has also been found to correlate negatively with a more general measure of psychopathy.

Neuroticism and Health

Neuroticism is well applied in personality models, but it is most informative in applications of health because it is suggested to be a universal accompaniment of abnormal functioning. Unique correlations between neuroticism and disorders make the dimension useful in

diagnosing disorder-specific characteristics. For instance, neuroticism is associated with autonomic fluctuations (unconscious or involuntary irregularities) and hazardous health behaviors, thus, personality is linked to health and illness (e.g. neurotic individuals are more likely to display unhealthy behaviors such as smoking cigarettes).

Neurotic individuals are likely to be hypochondriacs and have a fear of illness and disease. Unfortunately, in addition to these irrational thoughts, they have a higher likelihood of developing various forms of psychopathology (post-traumatic stress disorder, schizophrenia, etc.) and a variety of physical illnesses (hypertension, diabetes, etc.) than individuals lower in neuroticism. Those higher in neuroticism respond more poorly to environmental stress, are likely to interpret ordinary situations as threatening, and tend to feel overwhelmed by minor frustrations. Neurotic individuals are often dissatisfied with their selves and feel inadequate, which leads to low ratings on measures of subjective well-being, academic satisfaction, job satisfaction, performance motivation, and self-efficacy. The causes of these associations between neuroticism and subjective experiences are still unclear and research in this area is limited.

Individuals higher in neuroticism typically consider themselves to be in poorer health than those lower in neuroticism, which may be due to greater self-focused attention and bias toward negative affect. Those who have greater self-focused attention are more likely to detect changes in their physical health, whether real or imagined. Research has shown that self-focused attention is a significant mediator of reporting symptoms in individuals high in neuroticism, which is a product of greater attentional bias toward negative information about the self. Thus, individuals on the high end of neuroticism tend to report more symptoms about the self.

Sex Differences and Correlations to Other Traits

In a study of neuroticism, the trait was measured in two ways. First, neuroticism was measured in natural language terms, namely adjectives (e.g. tense, anxious, nervous, etc.). Second, neuroticism was measured using traditional inventory items, namely sentences and descriptive phrases. Traditional inventory items include sex-free descriptions, which do not relate to the opposite sex (e.g. "Do lots of things annoy you?") as well as sex-related descriptions, which include the opposite sex (e.g. "Do you often feel lonely?"). No overall significant sex differences were found when natural language terms were used to measure neuroticism, which suggests that adjectives are better indicators of sex-free neuroticism than are traditional inventory items. Traditional inventory items may be more abstract and ambiguous due to their reliance on personality-relevant statements, which may lead to confusion in participants. Interestingly, women are consistently higher in neuroticism than are men in both sex-free and sex-related traditional inventory items (sex-free and sex-related items are described above).

Research has been conducted on neuroticism and one of the most highly studied personality traits: self-esteem. Self-esteem is defined as the state, trait, or attitude that one has toward the self. One study found a positive correlation between the measures of neuroticism and self-esteem, thus researchers assumed that both traits reflect a single underlying construct. This is not surprising because neuroticism and self-esteem have been included

in the same structure of past theoretical personality models. Another study measured the association between neuroticism and implicit and explicit self-esteem. In contrast to the previous positive population correlation found, this study observed a negative correlation between neuroticism and both implicit and explicit self-esteem. This negative correlation was consistent when both an experimenter and when a non-experimenter was used to observe neurotic behaviors. Thus, individuals high in neuroticism appear to be lower in implicit and explicit self-esteem.

In addition to personality traits, neuroticism has been studied using attachment styles. Attachment styles originate from early childhood experiences with a caregiver, and develop into individual differences in cognition, feelings, and behaviors that occur in adult relationships. Secure attachment styles develop in infants whose caregivers were present as a secure base during exploring and were available if the infant was in need. Secure individuals are comfortable with intimacy and autonomy as they mature. Anxious and avoidant attachment styles are grouped in insecure attachment. Anxious attachment styles develop when the caregiver is present but not always available to the infant. Anxiously attached individuals may value intimacy in relationships but are overly dependent on others. Lastly, avoidant attachment styles develop in infants whose care-givers were not present, and they become individuals who tend to prefer little intimacy and do not like to depend on others. To expand on these attachment styles and neuroticism, a moderately negative correlation has been found between neuroticism and a secure attachment style, whereas a positive correlation is evident between neuroticism and insecure attachment styles. Thus, individuals who are securely attached tend to be lower in neuroticism, and individuals who are anxiously or avoidantly attached are higher in neuroticism. Indeed, all five facets of neuroticism have exhibited a moderately positive correlation with an anxious attachment style.

Previous studies have shown that neural activity is influenced by neuroticism in early phases of affective processing, and that neuroticism is related to poor emotion regulation. This relationship then perpetuates the characteristics of neurotic individuals. Individuals higher in neuroticism experience greater reactivity to stimuli, which makes them more prone to vary their cognition and behaviors. Consequently, the brain activity in individuals higher in neuroticism differs compared to those lower in neuroticism. For individuals with higher scores in neuroticism, the brain region that shows considerable individual differences is the parietooccipital region of the right hemisphere. When individuals high in neuroticism process negative visual stimuli, more varied brain activity is observed in the right hemisphere in comparison to the left hemisphere. In particular, women, who have overall been consistently higher in neuroticism than men show greater differences between the two sides of the brain. Further, women who are rated higher in neuroticism show a generic activity pattern in the left frontal area compared to varied activity in the right, and women who are rated lower in neuroticism show fewer hemisphere differences with positive images. These findings suggest an interaction between neuroticism and negative visual stimuli, where neurotic individuals use different strategies for processing negative stimuli. In conclusion, the differences in hemispheric activity suggest that the left and right side of the brain contribute in unique ways toward affective processing in individuals high in neuroticism.

Obsessive Personality

Christina Gray and Emma A. Climie

University of Calgary

Obsessions

Obsessions refer to unwanted, recurrent, and intrusive thoughts, impulses, and/or images that lead to marked anxiety and distress (Piacentini, Chang, Snorrason, & Woods, 2014). Obsessions commonly fall under a range of fear-related categories. For instance, obsessions may include fears about contamination, such as being concerned that one has been infected with pathogens. Obsessions may also include impulses to harm others or oneself, such as thoughts of stabbing a friend or family member. Excessive doubt obsessions may include being uncertain whether one has fully completed a task. Obsessions may involve disturbing images and thoughts, including images of violent scenes. Finally, obsessions may involve inexplicable experiences of incompleteness or feeling that things are not right, such as feeling that surroundings in one's environment are unsymmetrical (Piacentini et al., 2014). Obsessive symptoms frequently co-occur with compulsive symptoms, which are repetitive behaviors or mental activities that are intended to reduce anxiety associated with obsessions (Piacentini et al., 2014). For example, if an individual experiences contamination obsessions, they may engage in repetitive and excessive washing rituals to reduce their contamination-related anxiety (see Compulsions).

Obsessive symptoms have a complex neurobiological basis and etiological development. Structural abnormalities have been found in the frontostriatal neural circuits for individuals presenting with these symptoms. Furthermore, abnormalities in glucose metabolism and regional cerebral blood flow have been found in the basal ganglia, cingulate cortex, and orbitofrontal cortex of individuals with obsessive–compulsive related symptoms (Chamberlain, Blackwell, Fineberg, Robbins, & Sahakian, 2005). Both genetic and environmental factors play a role with influencing the etiology of obsessive symptoms. Twin studies have found that additive gene effects (i.e. the severity of obsessive symptoms is influenced by many genes that additively combine their effects) and non-shared environment (i.e. experiences that are not shared by both members of a twin pair) account for most of the variance in obsessive–compulsive symptoms (Taylor, 2011). Gene–environment

interactions significantly predict variance in obsessive–compulsive symptoms, and both obsessive–compulsive symptoms and negative emotionality have shared genetic variance (Taylor, 2011).

Theoretical Frameworks

There have been a number of theoretical frameworks proposed to explain the nature of obsessive symptoms. These include biological models, cognitive models, and cognitive-behavioral models.

Biological models emphasize the association of obsessive symptoms with functional and structural abnormalities in the brain, specifically the cortical-striatal-thalamic-cortical (CSTC) circuitry (Rosenberg, MacMaster, Mirza, Easter, & Buhagiar, 2007). Under the biological model, it is proposed that obsessive symptoms stem from an imbalance in the production and inhibition of thoughts relating to neural pathways within the CSTC circuitry.

Cognitive models note that obsessions are caused by misinterpretations of intrusive thoughts where one considers these thoughts to be highly significant. This valuing of intrusive thoughts as being highly significant results in an increase in obsessions. Under the cognitive framework, a dimensional perspective is taken where obsessions are extreme variants of obsessional intrusive thoughts.

The cognitive-behavioral framework, however, has received the most empirical support (Abramowitz, Taylor, & McKay, 2009). Under this framework, intrusive thoughts are considered normal aspects of the human mind; however, dysfunctional core beliefs lead to maladaptive appraisals of the intrusive thoughts (Piacentini et al., 2014). These maladaptive appraisals lead to emotional responses that play a role with developing and maintaining obsession symptoms. Collectively, these frameworks shed light on the complex biopsychosocial etiology of obsessive symptoms.

Abnormal versus Normal Obsessions

Experiencing concerns and anxious thoughts are common occurrences for many individuals. Encountering stressful circumstances and events are often daily occurrences and addressing experiences of stress and anxiety is a part of human experience. The ability to cope with one's stress and anxiety may be more difficult for individuals who have a predisposed sensitivity to anxiety, presenting a tendency to attribute anxiety and stress to more daily events (e.g. grocery shopping for an upcoming party, driving in rush-hour traffic, etc.) than would those who are better able to cope with anxiety and stress. Stressful or traumatic life events are known to influence the development of obsessive and compulsive related symptoms.

Intrusive thoughts and cognitions have been found to have a high incidence in typical populations, providing support for the division between normal and abnormal obsessions. In general, the distinction between normal and abnormal obsessions is dependent on the individual's ability to cope with and address these obsessional thoughts. Obsessional thoughts that may be experienced in a normal manner include intrusive thoughts that

provoke anxiety, but the individual is able to disregard these thoughts or resolve their experienced anxiety with minimal effort or disruption in their daily functioning. Situations in which individuals are unable to block out the unwanted obsessions warrant further clinical investigation.

Measuring Obsessions

There are several methods used to measure obsessions, and obsessions are commonly evaluated during the assessment process for Obsessive–Compulsive Disorder symptoms. These include diagnostic interviews, self-report measures, and questionnaire inventories administered by clinicians. Diagnostic interviews are used to differentiate between and assign diagnoses according to *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (DSM-V; American Psychiatric Association (APA), 2013). Self-report instruments allow for quick and independent administration to screen for symptoms; examples of these measures include the Obsessive Compulsive Inventory-Revised (OCI-R), the Yale-Brown Obsessive–Compulsive Scale-Self Report (Y-BOCS), and the Leyton Obsession Inventory Short Form.

Impact on Individuals

Obsessions have a significant impact on daily functioning in multiple capacities. By their nature, obsessions include images, thoughts, and ideas that continuously reoccur. Individuals experiencing obsessions may feel that they are unable to escape from their repetitive obsessions despite efforts to distract themselves and deter their thoughts. Focusing on obsessions may contribute to heightened anxiety and stress levels, making it difficult for individuals with obsessions to place full attention on tasks that they are completing in the work place, such as completing a business proposal, or in their home environment, such as planning and preparing for renovations. If obsessional intrusive thoughts significantly and regularly impair daily functioning, then an individual may be experiencing obsessions that are characteristic of psychological disorder.

Connection to Psychological Disorders

Several disorders include obsessions as a part of diagnostic criteria in the DSM-V (APA, 2013). Three notable disorders include Obsessive–Compulsive Disorder, Schizophrenia, and Autism Spectrum Disorder (ASD).

Obsessive–Compulsive Disorder (OCD) is a chronic, debilitating and severe clinical neurodevelopmental disorder that typically has onset in late adolescence to early adulthood (APA, 2013). Individuals with OCD experience obsessions due to a stressful event or for no apparent reason. These intrusive obsessions are more than excessive worries to the individual experiencing them and attempts to neutralize, suppress, or ignore the obsessions are made. Individuals with OCD recognize that their obsessions are not realistic and are merely

products of their mind; however, despite this knowledge, they struggle with controlling the obsessions. An individual with OCD will often engage in compulsions, or repetitive behaviors and mental acts, in response to their obsessions.

As a neuropsychiatric disorder, *Schizophrenia* involves interferences in social related-ness, perception, and cognition. The disorder is characterized by positive symptoms including disorganized speech/behavior, delusions, and hallucinations, as well as negative symptoms that include social withdrawal, anhedonia, and affective flattening. The presence of obses-sive compulsive (OC) symptoms in schizophrenia has been controversial, and it is thought that these symptoms may form an OC subgroup within the disorder. Individuals with schizophrenia may experience obsessions similar to those in OCD (e.g. contamination, reli-gious, aggressive, sexual) either with or lacking accompanying compulsions (e.g. cleaning, repeating, arranging). Further research is needed to understand the clinical and neurobio-logical significance of OC symptom presentation in schizophrenia (Hwang, Yum, Losonczy, Mitchell, & Kwon, 2006).

Autism Spectrum Disorders (ASD) is a neurological disorder characterized by impair-ments in social communication and interaction as well as restrictive interests and/or behavioral patterns. Those with ASD who experience obsessions may present an interest in a topic that has abnormal intensity and duration. For example, children with higher func-tioning ASD often learn many details about a topic they are extremely focused on (e.g. dinosaurs, construction vehicles), are preoccupied with this topic for a prolonged period of time, and display strong opinions toward it. Individuals with ASD may develop obsessions as a way to relax, cope with uncertainties, and use their obsessional interest as a way to converse and engage in social interactions. Additionally, those with ASD may also present sexual obses-sions involving perseveration on sexual themes as well as obsessions relating to stalking behaviors.

Treatments

Although it is difficult to fully eliminate obsessions, there are several options for treat-ment, including cognitive-behavioral therapy, pharmacotherapy, and brain modulation. Given that obsessions are intrusive thoughts, cognitive-behavioral therapy (CBT) is commonly used to treat obsessions. This form of therapy allows individuals to examine their obsessional thought patterns and consider alternative approaches to managing and eliminating these problematic thoughts. Foundational to CBT is the notion that obsessional intrusive thoughts are universal. CBT is the primary treatment for OCD and has been highly effective when combined with pharmacotherapy (Olatunji, Davis, Powers, & Smits, 2013).

Pharmacotherapy, also referred to as medication treatment, involves the action of pre-scription medications to block serotonin reuptake in the brain. Non-selective serotonin reuptake inhibitors (e.g. clomipramine) and selective serotonin reuptake inhibitors (e.g. citalopram, fluoxetine, paroxetine) are commonly used to treat OCD symptoms. Pharmacotherapy is most often effective when combined with other forms of psychological treatments, including CBT.

Brain modulation involves a range of techniques which include deep brain stimulation and transcranial magnetic stimulation. This form of treatment is often used to treat OCD symptoms in patients who do not respond to alternate treatment options. Brain modulation treatments involve sending electrical impulses to areas of the brain in an attempt to alter obsessive–compulsive thought and behavior patterns. Although brain modulation techniques have displayed promising results, further empirical research is needed to support their efficacy as an OCD treatment option.

Optimism and Pessimism

Conceptualization, Personality Correlates, and Contextual Considerations

Optimism and Pessimism: An Overview

As the implications and usefulness of positive psychology have gained momentum in the psychology literature, optimism and pessimism have become important constructs for understanding how positive and negative expectations may affect mental and physical health. *Optimism* is the disposition to have expectations of future outcomes that are generally positive, whereas *pessimism* is the disposition to have expectations that future outcomes will likely be negative. Importantly, optimism/pessimism is often understood as a personality trait because an individual's disposition toward optimism or pessimism remains relatively stable over time, given that no major negative life events or traumas occur. Optimism has been found to be inversely related with hopelessness and may also act as a buffer for the negative effects of stressful life events. Pessimism, on the other side of the spectrum, has been associated with maladaptive traits like obsessive–compulsive disorder (OCD) and neuroticism (Niemeyer, Moritz, & Pietrowsky, 2013). Moreover, researchers have consistently found that optimism has a positive effect on physical health outcomes, like cardiovascular health and immune response (Tindale et al., 2009), while pessimism has been associated with poor physical health outcomes, including immunosuppression and passive self-care (Van Dyk & Nelson, 2014).

Owing to the positive impact of optimism and negative impact of pessimism on numerous aspects of health, researchers have gained interest in identifying the characteristics of optimists versus pessimists. This chapter has three main goals: (1) to identify the different types of optimism and pessimism; (2) to review the current literature identifying personality traits that tend to be associated with optimism and pessimism; (3) to address the importance of thinking carefully about the conceptualization of these constructs and the role of culture when studying optimism and pessimism.

Types of Optimism and Pessimism

The research on optimism and pessimism has identified distinct types of optimism and pessimism. It is important to know these distinctions and how they may be correlated with different personality traits in order to better understand the impact and effects of optimism and pessimism. The most common conceptualization of optimism is *dispositional optimism,* or the stable, cognitive trait of positive future-thinking. *Situated optimism* defines the tendency for individuals to be more or less optimistic depending on the situation and personal needs. For example, an individual may be more optimistic in a situation where there is a much higher chance of a favorable outcome than in a situation where the likelihood of a positive outcome is very small. Furthermore, *unrealistic optimism* is the tendency for individuals to believe they are at a lower risk than their peers for adverse health outcomes across numerous domains, regardless if they have legitimate evidence to support this belief or not. Some research has found associations with unrealistic optimism and worse health outcomes because individuals do not take proper health precautions or seek treatment due to their unrealistic optimism (Weinstein, 1987), while others have not found convincing evidence to support the idea of unrealistic optimism being maladaptive (Harris & Hahn, 2011). Overall, it is important to identify the type of optimism being examined when discussing personality correlates. For instance, because the cognitive processes behind dispositional optimism and unrealistic optimism are quite different, different personality types may be more likely to have one type of optimism over another.

Pessimism has also been differentiated into different types. *Dispositional pessimism* is the constant personality trait of generally expecting negative outcomes. *Defensive pessimism* involves holding unrealistically low expectations in certain situations in order to gain control over anxiety and consequently perform better. This behavior can be seen as adaptive as it "highlights the need to account for the individual's capacity for interpreting situations strategically in order to emerge relatively unscathed" (Norem & Cantor, 1986, p. 1208). Thus, it is seen as useful for mental health in situations where the likelihood of a positive outcome is especially dire. Additionally, *unrealistic pessimism* is defined as the tendency for individuals to overestimate the likelihood of experiencing negative outcomes and expect more positive outcomes for their peers than themselves. For example, unrealistic pessimism has been associated with OCD, which can be especially maladaptive for mental and physical health (Niemeyer et al., 2013).

Identifying the distinct types of optimism and pessimism allows us to better understand how these cognitive functions may affect the behaviors and health of an individual. Some types of optimism are considered more adaptive than others, and some types of pessimism are considered more maladaptive. While much of the research has furthered our understanding of how optimism and pessimism affect psychological and physical health, it is less clear how these constructs are related to specific personality traits. Recent research has investigated this question, and we will review the findings in the next section.

Personality Correlates

One theory utilized by researchers to understand how optimism is related to various personality types is the well-validated theory of the Big Five personality traits. In one study, researchers found optimism to be associated with four of the five personality traits

(i.e. emotional stability, extraversion, agreeableness, and conscientiousness; Sharpe, Martin, & Roth, 2011). Indeed, optimism has commonly been linked to low levels of neuroticism and high levels of extraversion and positive emotionality (Boland & Cappeliez, 1997), and Milligan (2003) also found optimism to be positively associated with extraversion, agreeableness, and conscientiousness. On the opposite end of the spectrum, pessimists were found to have a personality profile consisting of high neuroticism and low levels of extraversion, agreeableness, and conscientiousness. Understanding these connections has allowed researchers to theorize potential pathways to optimism/pessimism that are created based upon the more influential presence of a Big Five personality trait. For example, Sharpe et al. (2011) argued that a more agreeable nature likely leads to optimism through better social relationships and satisfaction with life, and a more conscientious nature leads to optimism through believing in positive future experiences and working persistently in pursuit of goals.

Apart from the Big Five, optimism and pessimism have also been associated with other personality characteristics. Optimism has been linked to a slightly more dominant and warm interpersonal style (Smith, Ruiz, Cundiff, Baron, & Nealey-Moore, 2013) and more positive affect (Chang & Sanna, 2001). Pessimism, on the other hand, has been linked with higher levels of anxiety, more negative affect, and greater frequency of suicidal ideation (Hirsch, Walker, Chang, & Lyness, 2012). Optimists also tend to have more success with positive coping than pessimists, who often engage in avoidant coping (Taylor et al., 1992). Additionally, with regard to motivation, optimists tend to engage in approach motivation while pessimists are more likely to engage in avoidance motivation (Gibson & Sanbonmatsu, 2004). For example, this predisposition to approach motivation may be harmful for dispositional optimists in situations like gambling, where they may be more likely than pessimists to continue gambling if they are losing money. Moreover, defensive pessimists are likely to over-achieve and over-prepare, often resulting in positive outcomes due to their high motivation to avoid failing (Elliot & Church, 2003).

Overall, optimism tends to be associated with more extraverted and goal-oriented personality types, whereas pessimists tend to have more avoidant and neurotic personality traits. This knowledge is useful for interventions and treatment in that it allows clinicians to recognize an individual's predisposition for optimism or pessimism, and consequently help them use this level of optimism or pessimism to the benefit of their psychological health – be it through defensive pessimism or dispositional optimism.

Considerations for Optimism and Pessimism: Conceptualization, Culture, and Context

When thinking about optimism and pessimism, it is important to be aware of the debate over the conceptualization of this construct. Is it a bipolar, unidimensional construct or are they two distinct phenomena that should be measured separately? Scheier and Carver (1985) developed the Life Orientation Test (LOT), which measures optimism/pessimism as a unidimensional construct, with one end indicating optimism and the other end indicating pessimism. Other researchers, however, have found little overlap between optimism and pessimism and therefore argue that they should be measured as distinct constructs (Glaesmer et al., 2012). It is not the purpose of this chapter to cast a vote in one direction or

the other, but it is important to note the implications of conceptualizing pessimism as simply the lack of optimism versus seeing it as its own personality dimension. With regard to treatment and intervention, knowing how an individual's personality disposes him or her to view future expectations, or how he or she is likely to pursue goals based on an optimistic or pessimistic nature, can be very helpful for therapists and clinicians when deciding on treatment plans. Regardless of how the measure is conceptualized, it is important to take the researcher's constructs thoughtfully into account when interpreting findings in the optimism/pessimism literature.

It is also important to consider cultural differences when discussing optimism and pessimism. When looking through a Western lens, it is easy to criminalize pessimism and see it as extremely maladaptive while optimism is extremely adaptive. However, this may not be the case in all cultures. For example, Chang (1996) suggested that pessimism might not be as detrimental for Asian Americans as it is for European Americans. Moreover, levels of optimism and pessimism may differ by culture and region. For example, individuals from Eastern cultures are more likely to have positive expectations for others and negative expectations for themselves. This is likely due to the collectivist culture that is developed in most Eastern societies, which emphasizes others and the community, rather than the individualistic society often found in Western cultures. Sources of optimism may also be different based on culture. In one study, Kuwaitis reported greater spiritualized hope than Americans, suggesting their optimism is likely more faith-based than Americans' optimism (Abdel-Khalek & Scioli, 2010). Taken together, these findings suggest that culture is an essential variable to consider when studying optimism and pessimism in people of all cultures, races, and religions.

Next Steps

The study of optimism and pessimism is essential to understanding how our disposition to think positively or negatively about the future can affect all aspects of our lives. Discovering the effects of optimism and pessimism in individuals is useful for both mental and physical health treatments because it allows us to see how this personality trait can impact the outcomes of clients. More research is needed to further understand how these personality traits are correlated and how they work together to produce adaptive or maladaptive behavior. Further work is also needed to try and solve the debate over how to conceptualize optimism/pessimism. Lastly, it is necessary to continually keep culture in mind when moving this field forward. There is more nuance and complexity to optimism and pessimism than just positive or negative thoughts, so learning how these dimensions affect our emotional and physical functioning has positive implications for more effectively improving the overall well-being of individuals.

Perfectionism

Martin M. Smith and Samantha Chen

University of Western Ontario

Frost et al.'s (1990) Multidimensional Perfectionism Scale

Frost et al. (1990) conceptualized perfectionism as being composed of six dimensions: *personal standards* (e.g., "I set higher goals than most people"), *concerns over mistakes* (e.g., "People will probably think less of me if I make a mistake"), *doubts about actions* (e.g., "I tend to get behind in my work because I repeat things over and over"), *organization* (e.g., "I am a neat person"), *parental expectations* (e.g., "Only outstanding performance is good enough in my family"), and *parental criticisms* (e.g., "As a child I was punished for doing things less than perfect"). Individuals with high concerns over mistakes perceive minor flaws in their work or performance as indicative of failure. According to Frost et al. (1990), concerns over mistakes cause perfectionists to strive for success to avoid failure, rather than a need for achievement. People with high doubts about actions have nagging uncertainties about the quality of their performance. Doubts about actions also lead perfectionists to repeat tasks, as well as causing a reluctance to complete tasks. People with high personal standards strive toward unrealistically lofty goals. According to Frost et al. (1990), personal standards are not in and of themselves pathological and may stem from a positive outlook on life. Individuals with high parental expectations are theorized to have grown up in environments where obtaining parental approval and love was conditional on their performance. Moreover, people with high parental criticism are theorized to have grown up in environments where parental figures engaged in harsh criticisms whenever performance was less than perfect.

Subsequently, research supports personal standards, doubts about actions, and concerns over mistakes as core characteristics of perfectionism. Indeed, factor analytic investigations suggest concerns over mistakes is the cornerstone of perfectionism, as it consistently emerges as the "strongest" factor. In contrast, organization is only weakly related to the other perfectionism dimensions (e.g. concerns over mistakes) and thus is not considered a core characteristic of perfectionism. Furthermore, organization is a facet of conscientiousness. Accordingly, the inclusion of organization as a component

of perfectionism is problematic. Perfectionism researchers also no longer consider parental criticism and parental expectations as facets of perfectionism, as parental criticism and parental expectations represent developmental antecedents, not core characteristics, of perfectionism.

Hewitt and Flett's (1991) Multidimensional Perfectionism Scale

In consideration of the social and personal dimensions of perfectionism, Hewitt and Flett (1991) distinguished between three overlapping, albeit non-redundant, forms of perfectionism: *self-oriented perfectionism* (e.g. "One of my goals is to be perfect in everything I do"), *socially prescribed perfectionism* (e.g. "My family expects me to be perfect"), and *other-oriented perfectionism* (e.g. "If I ask someone to do something I expect it to be done flawlessly"). Self-oriented perfectionism involves self-directed behavior and internally motivated beliefs that it is important to be flawless, and strive for perfection. People with high self-oriented perfectionism set lofty goals, strive to do everything perfectly, and have overly negative reactions when their performance falls short of their standards. In contrast, socially prescribed perfectionism is a social evaluative tendency to believe that being perfect is important to others and that others will be disappointed if they fall short of their expectations. Both self-oriented and socially prescribed perfectionism involves harsh criticism of the self. However, self-oriented perfectionists are critical of their own behaviors and performance, whereas socially prescribed perfectionists perceive that other people are critical of their behavior and performance.

Other-oriented perfectionism is an outwardly directed form of perfectionism in which one harshly demands perfection from other people. Compared to self-oriented perfectionism and socially prescribed perfectionism, other-oriented perfectionism does not involve self-criticism. Other-oriented perfectionists tend to be highly critical toward others, which leads to a plethora of interpersonal problems such as low relationship satisfaction. Historically, other-oriented perfectionism has received less attention than self-oriented perfectionism and socially prescribed perfectionism. Despite this, there has been a renewed interest in other-oriented perfectionism, in part due to research suggesting it is a defining feature of narcissism (Smith, Sherry, Chen et al., 2016).

The Two-Factor Model of Perfectionism

Theory and evidence have converged to suggest that two higher-order factors underlie and account for shared variance among many of the lower-order facets proposed by Hewitt and Flett (1991) and Frost et al. (1990). This model is referred to as the Two-Factor Model of Perfectionism and stems from the finding that when Hewitt and Flett's (1991) and Frost et al.'s (1990) Multidimensional Perfectionism Measures are factor analyzed, results consistently reveal a two-factor solution. One factor, referred to as *perfectionistic strivings*, accounts for shared variance between self-oriented perfectionism and personal standards. A second factor, referred to as *perfectionistic concerns* (or self-critical perfectionism),

accounts for shared variance among socially prescribed perfectionism, concerns over mistakes, doubts about actions, and self-criticism. Research supports the validity of the Two-Factor Model of Perfectionism. The two-factor model emerges across a variety of different perfectionism measures (e.g. the Clinical Perfectionism Questionnaire), and generalizes across non-English speaking populations. Many also consider perfectionistic strivings to be a positive form of perfectionism and perfectionistic concerns to be a negative form of perfectionism.

Indeed, perfectionistic strivings and perfectionistic concerns correlate positively ($r_{xx} = .45$ to .65), but nonetheless, have divergent patterns of associations with positive and negative psychological outcomes. In general, after removing the overlap with perfectionistic concerns, perfectionistic strivings are associated with positive outcomes such as test performance. As such, perfectionistic concerns appear to suppress the association between perfectionistic strivings and positive psychological outcomes. However, it is important to note perfectionistic strivings are not solely associated with positive psychological outcomes. For instance, perfectionistic strivings are tied to narcissistic grandiosity (Smith, Sherry, Chen et al., 2016) and place people at risk for increased depressive symptoms (Smith, Sherry, Rnic et al., 2016).

In contrast, perfectionistic concerns are clearly a negative form of perfectionism, robustly related to negative outcomes such as paranoia, negative affect, procrastination, low trait emotional intelligence, suicidal ideation, and interpersonal problems. Also, perfectionistic concerns have strong theoretical and empirical links with Axis I disorders (e.g. depression; Smith, Sherry, Rnic et al., 2016). Research suggests perfectionistic concerns are maintained and manifested through insecure expressions such as intimacy avoidance, disengagement from decisions and actions, and suspiciousness.

But what causes the divergent pattern of positive and negative associations between perfectionistic strivings and perfectionistic concerns? In part, perfectionistic strivings and concerns divergent patterns of correlations can be accounted for by individual differences in the use of coping strategies when confronted with a perceived stressor. Specifically, perfectionistic concerns are strongly related to the use of maladaptive coping strategies (e.g. emotion-oriented coping) that subsequently inhibit effective regulation of day-to-day stressors and consequently, increase the likelihood of experiencing maladaptive psychological outcomes such as depression. Conversely, perfectionistic strivings are associated with the use of adaptive coping strategies (e.g. task-oriented coping), which facilitate effective stress regulation, and increase the likelihood of experiencing positive psychological outcomes such as life satisfaction.

Confusion often arises in regard to whether perfectionism is a form of conscientiousness. While perfectionistic strivings in many ways are a form of "hyper-conscientiousness," perfectionistic strivings also contain characteristics that fall outside the domain of conscientiousness, such as a compulsive need for things to be perfect and precise. In contrast, perfectionistic concerns are associated with neuroticism and low agreeableness but contain additional components capturing variance related to feelings and thoughts that others place unduly harsh demands on them to be perfect. Finally, it is notable that perfectionistic strivings and perfectionistic concerns add incrementally to the prediction of numerous psychological outcomes, such as depression, above and beyond the five-factor model of personality.

Within-Person Combinations of Perfectionistic Strivings and Perfectionistic Concerns

For the vast majority of people, perfectionistic strivings and perfectionistic concerns co-occur and produce three meaningful within-person subtypes: adaptive perfectionists (high perfectionistic strivings and low perfectionistic concerns), maladaptive perfectionists (high perfectionistic strivings and high perfectionistic concerns), and non-perfectionists (low perfectionistic strivings). This is referred to as the Tripartite Model of Perfectionism. Research indicates that relative to adaptive perfectionists and non-perfectionists, maladaptive perfectionists experience significantly higher levels of depression, anxiety, stress, and negative affect. Moreover, some research suggests that adaptive perfectionists experience greater life satisfaction than non-perfectionists. When asked to describe themselves, adaptive perfectionists report living fast-paced lives, working tirelessly toward goals, striving for superiority, and being forceful, dominant, and socially ascendant. In contrast, maladaptive perfectionists report being easily discouraged, inept, cynical, lonely, and prone to anger and frustrations.

Clinical Implications of Perfectionism

Perfectionism has been shown to play a significant role in the development and maintenance of various forms of psychopathology. For instance, perfectionism has been positively related to an array of anxiety disorders, such as panic disorder, agoraphobia, general symptoms of anxiety, and worry. The most robust relationship appears to be between perfectionism and social anxiety, and perfectionism has been posited to play a central role in cognitive models of social phobia. Perfectionism has also been shown to play an important role in the development of obsessive–compulsive disorder. In addition, numerous studies have indicated a positive association between perfectionism and depression (e.g., Smith, Sherry, Rnic et al., 2016). This relationship may be mediated by a number of factors including perceived control and self-esteem. Moreover, perfectionism has been associated with increased levels of hopelessness and suicidality. Perfectionism is also thought to be a key factor with regard to eating disorders, and has been identified as a specific risk factor for the development of both anorexia nervosa and bulimia nervosa. Likewise, perfectionism is considered a hallmark feature of, and is included as one of the diagnostic criteria for, obsessive–compulsive personality disorder.

   Perfectionism also interferes with the efficacy of many psychological treatments. Higher levels of perfectionism have been shown to be negatively associated with therapeutic outcomes and are related to challenges with establishing an effective therapeutic relationship between the client and the therapist. Specific dimensions of perfectionism have been shown to be directly linked to psychological distress and are uniquely associated with various forms of psychopathology and maladjustment. For instance, socially prescribed perfectionism is the component of perfectionism that is most consistently linked with negative psychological outcomes, including depression, anxiety disorders, personality disorders, low self-esteem, and suicidality. Self-oriented perfectionism has been associated with depression, eating disorders, suicidal ideation, as well as academic and achievement

problems. In contrast, other-oriented perfectionism has been linked with low relationship satisfaction and poor dyadic adjustment. Furthermore, consistent findings have been found suggesting that it is the negative self-evaluative dimension of perfectionism that is most closely associated with psychopathology.

Conclusion

Perfectionism is a multidimensional construct, predominantly measured by Frost et al.'s (1990) and Hewitt and Flett's (1991) Multidimensional Perfectionism Scales. Based on these measures, a two-factor model of perfectionism has been proposed which includes perfectionistic strivings and perfectionistic concerns. Likewise, perfectionism and its trait dimensions act as vulnerability factors in various forms of psychopathology, such as depression. Future research should continue to investigate the dimensions of perfectionism in relation to one another and explore the mechanisms by which these dimensions relate to important psychological outcomes.

Persistence, Personality Correlates

Annamaria Di Fabio and Alessio Gori

University of Florence, Italy

Definition of Persistence

Persistence could be defined as a personality trait related to perseverance in the pursuit of purposes in spite of fatigue or frustration and in the seeking of rewards even when the expected outcome is only rarely successful (Cloninger, Svrakic, & Przybeck, 1993). In other terms, persistence refers to a construct that includes the ability to maintain a high motivation to reach a goal, also in the absence of an immediate external reward.

Over the last 20 years, persistence has emerged in psychology as a pattern of attitudes that facilitates goal achievement and it could be considered a higher order construct that contains several psychological aspects including eagerness of effort, work hardenedness, ambition and perfectionism. Individuals with high levels of persistence tend to be perseverant, well-motivated, hard-working, and persistent; they tend to respond to signals of anticipated reward and to intensify their efforts in return for anticipated reward; they usually offer themselves as volunteers to do something; they desire to work on different aspects and they tend to work harder when faced with problems in their work; they are generally disposed to make sacrifices to obtain success; they are able to persevere in a perfectionistic way in response to intermittent reward. Besides, high levels of persistence seem to be linked to stability, alacrity, industriousness, and sense of duty.

Persistence has been studied in different fields of psychology, including personality, psychobiology, psychopathology, and organizational psychology.

Measurement of Persistence

Persistence can be measured with specific scales or multidimensional questionnaires (Temperament and Character Inventory, also in its revised form; Self-Control Measure; Action Control Scale).

The most popular measure to assess persistence is the Temperament and Character Inventory-Revised (TCI-R). The TCI-R is a 240-item self-administered questionnaire designed to measure the dimensions of four temperaments (Novelty Seeking, Harm Avoidance, Reward Dependence and Persistence) and three character factors (Self-directedness, Cooperativeness, and Self-transcendence).

Subtypes of Persistence

Subtypes of persistence reflect the manner in which individuals express the characteristics of persistence. Expressions of persistence could be perseverance in achieving tasks despite tiredness and the continuing expectation and pursuit of rewards even when the expected outcome is only rarely successful (Cloninger et al., 2013). Other expressions of persistence can be determination (the quality of being resolute and firm in reaching goals), conscientiousness (care taken in doing what you are supposed to done) and ambitiousness (eagerly desirous of achieving or obtaining success). Besides, perfectionism is another aspect of being persistent that can be defined as the striving for flawlessness and reaching high performance standards, and at the same time a critical self-evaluation (Flett & Hewitt, 2002).

Other characteristics of persistence are the quality of being eager for efforts and the tendency to work hard. By contrast, people with low levels of persistence are described as changeable, irresolute and easily discouraged (Cloninger et al., 1993).

Similarities of Persistence to Other Constructs

In the sphere of personality and individual differences, the dimensions that would appear most similar to persistence are those of grit, industriousness, tenacity, hardiness, endurance, and ego-strength.

Grit can be defined as perseverance and passion for long-term goals. Although perseverance is considered in the construct of grit, it seems related to sustained efforts in projects that take a long time to complete; this emphasis on long-term projects is not present in the construct of persistence which seems more oriented toward a perseverance in reaching goals despite frustration. In fact, in persistence the role of sacrifice in the pursuit of purposes seems to be stronger than in the grit construct, while grit seems to pay more attention to the consistency of interests.

The construct of industriousness is also related to perseverance and determination in performing a task, but following the learned industriousness theory, industriousness is developed over time through a history of reinforcement. Unlike, persistence does not seem necessarily linked to any kind of reinforcement.

With regard to tenacity, that comes from scheduling a goal beforehand, persistence does not necessarily pay attention to the pursuit of an intended goal in advance; besides this, tenacity is expressed most strongly in goal domains that are central to the person's identity or life design, as well as in areas of performance. In addition, it seems that tenacity would

be more focused on the extrinsic motivation, while persistence seems to be a part of intrinsic and also extrinsic motivation.

Another construct that presents similarities with persistence is hardiness, namely a personality construct that describes people who tend to remain healthy under pressure and which includes several components like commitment, control, and challenge. These aspects of the hardiness construct, which arose from existential psychology, seem to help individuals face stressful situations and remain healthy under stress, unlike persistence that is goal-oriented and allows the individual to change their positive situation (context) through the achievement of the objective.

As regards endurance, which could be defined as the habit of finishing what someone has already started, it is possible to view it as a basic trait of persistence; this indicates that probably the endurance dimension could be part of the higher order construct of persistence.

Another construct that presents similarities with persistence could be that of ego-strength, derived from a clinical theoretical tradition. Ego-strength is the capacity to maintain emotional stability, to cope with stress, and to defer gratification; in clinical psychology, it is useful to identify subjects which can benefit from psychotherapy. Persistence, despite having similar aspects with ES, seems more focused in the perseverance of pursuit of goals.

Explanations of Persistence

Explanations of persistence include, biological, personality, and psychopathological contributions.

Biological Correlates of Persistence

Studies have converged on the finding that individual variations of personality dimensions are widely genetically determined (Cloninger, 2000).

According to Gardini and colleagues (2009), personality dimensions such as novelty seeking, harm avoidance, and persistence seem to be heritable, with 25% of variation transmissible from parent to child, and another 25% of variation dependent on non-linear interactions among multiple genes (Cloninger, 2000), relatively stable across time, and dependent on genetic and neurobiological factors (Gardini, Cloninger, & Venneri, 2009).

Neuroscience research suggests that the neural circuitry underlying these systems is at least partially localized; people with the highest persistence scores had increases in activation in orbitomedial prefrontal cortex and ventral striatum (Gardini et al., 2009). Moreover, a significant positive correlation was found in the right paracentral lobule and parahippocampal gyrus, and in the left precuneus (Gardini et al., 2009). Likewise, it seems that specific groups of genes played a role in some personality traits and persistence had the highest variance explained for serotonin genes (e.g. Cloninger, 2000); higher persistence scores have been associated with the short allele of the promoter of the serotonin transporter and homozygosity in catechol O-methyltransferase (val/val or met/met genotypes) (e.g. Cloninger, 2000).

Personality and Psychopathology Correlates of Persistence

Persistence is one of the most controversial temperamental traits; high levels of persistence seem to be linked to stability, alacrity, industriousness, sense of duty and perfectionism, but can become maladaptive when the contingencies change rapidly.

In fact, on the one hand, highly persistent people also tend to be perfectionists, or at least feel they need to be the best at whatever they try to do (Fleet & Hewitt, 2002), without paying attention to the fact that this perfectionism and the exaggerated positive expectations can easily lead to compulsive self-doubt and excessively harsh judgments of themselves and others (Cloninger et al., 2012).

Some authors have suggested that persistence could be the key to discriminating people with anxiety disorders from those with mood disorders (Cloninger et al., 2012). This strong discriminant effect is the result of high persistence increasing both negative emotions and positive emotions in the same person (Cloninger et al., 2012). In other words, high persistence protects against mood disorders by increasing some positive emotions (such as happiness and being interested, active, and enthusiastic) but, at the same time and in the same person, it can increase the risk of anxiety disorders by enhancing negative emotions (such as feeling distressed, scared, upset, and nervous) (Cloninger et al., 2012).

With regard to affective disorders, a study showed that low persistence was a strong predictor of future depressive episodes and was also predictive independently of the baseline level of depression, providing prognostic value (Rosenström et al., 2014).

Some studies have also found that persistence was associated to conscientiousness (De Fruyt, Van De Wiele, & Van Heeringen, 2000), resilience, and positive emotionality.

Other researchers found that persistence was correlated to life satisfaction, happiness, and social support (Cloninger et al., 2011). Additionally, persistence was moderately and positively associated with the trait of self-transcendence measured with the Temperament and Character Inventory (TCI) and was negatively correlated with psychoticism in Eysenck's model (De Fruyt et al., 2000).

Dealing with Persistence

An important condition that allows high persistence to increase happiness occurs when people are highly accepting of themselves and others, with other characteristics like high self-directedness, high co-operativeness, and high self-transcendence; it seems that each of these traits can increase components of well-being (Cloninger & Zohar, 2011) and prevent the development of mood disorders, in particular depression (Rosenström et al., 2014). Although persistence is not a disorder, low persistence seems to be a strong predictor of future depressive episodes (Rosenström et al., 2014) and probably can contribute to sufficient affective discomfort and problems in personal lives. Indeed, people with low persistence seem to be changeable, irresolute, and easily discouraged. Approaches to helping individuals to enhance their persistence are probably those that focus on strengthening the human potential, like counseling or specific programs to increase self-motivation and perseverance. In our view, approaches to helping individuals to improve their persistence could be focused on the various subtypes and aspects of persistence. At first it could be important to understand if deficits concern the inability to identify the right signals of reward (cognitive), or are due to

an inability to recognize negative emotions such as distress, guilt, nervousness, or are derived from a lack of ambition or frustration tolerance. Concerning the inability to identify the right signals of reward it could be possible to train the subject to recognize the right incentives and give them a proper meaning, through positive or negative reinforcements. In the case of inability to understand emotions and the presence of negative emotionality, an emotional education program and training on how to change negative emotional states to positive ones could be the right approach.

Personality Development

Federica Andrei

University of Bologna

Personality can be seen as an organized way of feeling, thinking, and behaving which typifies a person's lifestyle and adaptation in a given society or culture. Even though personality has relevant elements of stability, it is not immutable, as it evolves throughout the lifespan by showing evidence of both continuity and change. The idea that personality is set in childhood and adolescence, and that it fully develops by the age of 30 has been maintained for a long time. On the contrary, current studies show that during midlife and old age mean-level developmental change of personality traits still occurs. Personality develops from a series of complex interactions between genotypically driven differences and environmental factors, which progressively lead the early temperament dimensions to develop into the personality traits observed in the different phases of life. Although little is known about how early-emerging individual differences become elaborated into what we call personality, there is a general consensus around the idea that the development of personality follows a dynamic and gradual course, rather than a clearly defined progression of discrete stages. At the same time, from a lifespan perspective this process shows enough structure and direction, marking progressive change and continuity throughout childhood, adolescence, adulthood, midlife, and old age, although trait instability might be more pronounced in certain life phases than others. However, not all individuals show the same developmental pattern over time, as there might be inter-individual differences in the direction, rate, and time of intra-individual personality change.

Infancy and Childhood

In the first few weeks of life, infants begin to show distinct individualities in their temperament, in their self-regulatory behaviors and in their predisposition toward positive and negative emotions: these elements constitute the basis from which personality develops. Contemporary interest in the patterns of temperamental development is largely due to the

insightful work of Chess and Thomas (1987), whose research had a substantial impact on the developmental study of temperament (see pages 1491–1496 of this volume for a more detailed discussion of temperament). As for adult personality, temperament in infancy and early childhood is influenced by both genetic contributors and environmental experiences, such as those with peers and educational system. Among the environmental factors, parents' responses to their infant's temperament are assumed to play a crucial role on the evolution of personality, with important long-term consequences. In fact, parents' responsive attitude influences relevant evolutionary goals in personality development, such as the quality of the caregiver-infant attachment bond (Ainsworth, 1979; Bowlby, 1980). Observational longitudinal studies on caregiver-infant relationships also found that caregiving behaviors impact the stabilization of early temperamental characteristics. For instance, inhibited children receiving intrusive, derisive, or overprotective parenting remain more consistently inhibited across time compared to inhibited children receiving other responses from their caregivers; parenting is also relevant for the development of an effective regulation of negative emotionality which is crucial for good attentional control, whose bias is implicated in higher levels of Neuroticism in adulthood. In a similar fashion with other aspects of development, as infants move into childhood their set of individual differences increasingly broadens and becomes more complex given the progressive acquisition of new and more sophisticated skills, and with the emergence of an agentic, goal-directed, self.

Adolescence

Adolescence can be seen as a relevant period for personality development, particularly given its rapid biological, social, and psychological transformation. Even though adolescence's boundaries have become increasingly difficult to define, pubertal biological changes, which appear around age 11 for girls and age 13 for boys, can be seen as markers of its beginning. Puberty has many influences over individuals' personalities, some of which are gender-specific, like in the case of the first signs of depression observed particularly in girls, and an increase in antisocial behavior recognized especially in boys. As children move into adolescence, their goals and motives become crystallized, and they become able to evaluate the worth and progress of the projects they set in many areas of their lives, such as friendship, school, and sport. These goal-directed tendencies structure their consciousness and shape their behavior across situations and over time. Yet, the emergence of self-esteem on the verge of this period of life has implications for the development of dispositional traits like extraversion and neuroticism. Adolescents work to establish coherent identities, and they develop more complex, abstract, and better differentiated self-concepts, thus revealing a rich and articulated portrait of psychological individuality. Normative changes in both youths' relationships with adults and peers, and in their attitudes toward social values and norms also emerge and shape identity development and exploration of different roles and possibilities. This is the time of life when the structure of personality begins to stabilize. Cross-sectional studies on the Big Five framework revealed that adolescents are higher in Extraversion and Emotional Stability and lower in

Agreeableness and Conscientiousness than adults. Additional evidence suggests that Openness increases in both cross-sectional and longitudinal studies.

Adulthood

During the period of "emerging adulthood" (i.e. ages 15 to 30; Arnett, 2000) people undergo a process of role changes which is in part historically and culturally determined. Most men and women are more prone to respect norms, become more socially competent, and less impulsive. The idea of normative developmental changes in personality functioning toward greater adaptation implies that with age individuals show a gradual shift upward in those dispositional traits associated with agreeableness, conscientiousness, and openness, and a decline in neuroticism. Both longitudinal and cross-sectional studies using multiple birth cohorts, with samples having different Western cultural backgrounds, supported the idea of normative changes in personality. Normative changes are categorized by significant individual differences which are influenced by several factors, such as gender. The existence of individual differences in change suggests the hypothesis that certain life experiences, including work and relationships, differentially contribute to normative developmental changes as well as shaping life trajectories and a person's adaptation during this time. From early to middle adulthood, people gradually appear to become more comfortable with themselves as adults, less inclined to moodiness and negative emotions, more responsible and caring, more focused on long-term tasks and plans, and less susceptible to extreme risk-taking and the expression of unbridled internal impulses. Longitudinal findings on personality change in adulthood showed that the increase in Openness and decrease in Emotional Stability continue for a while during young adulthood. Cross-sectional studies revealed that later on, Openness and Extraversion tend to decrease moderately until the age of 30 and more slowly thereafter, while Agreeableness, Conscientiousness, and Emotional Stability show a tendency to increase.

Midlife and Old Age

Studies on aging suggest that personality development might differ in different phases of midlife as a result of changes in life challenges, including a progressive shift from the establishment of new social roles to the maintenance and mastery of these roles. In early-old age, biological losses are present and noticeable, but as the end of one's life becomes more prominent they become remarkable. The rank-order stability of personality has been found to be lower in older adults than in younger ones, and the former have been also found to show stronger decreases in intellect, comparable with openness to experience, and agreeableness than those at the beginning of old age. Dealing with losses, such as the death of their partner, adjusting to a decline in overall health and to retirement, comprise the major developmental tasks of older adults. The experience of physical and cognitive decline occurring during this phase of life may lead individuals to select strategies for accomplishing goals that optimize their best skills and compensate for areas of weakness. At some point in the midlife years, adults appear to shift their perspective on life from one emphasizing expansion,

activeness, and information seeking to one emphasizing contraction, protection, and the quality of emotional life. With regard to this, there is evidence attesting that during midlife Conscientiousness and Agreeableness rise to their apex and Neuroticism may bottom out. Gender-specific findings show that during midlife, both males and females longitudinally decrease in Extraversion and increase in Emotional Stability, but only males decrease in Conscientiousness and Openness and only females increase in Agreeableness. Inter-individual differences in this process are reflected in the timing of this shift, in its domains of emergence, which can change among individuals. Similarly to the precedent phases of life, these personality changes arise from the continuous interaction between the individual and the environment.

Phobia

Caitlin J. Spencer

Western University, Ontario, Canada

Conceptualization and Diagnosis

Phobia is classified as an anxiety disorder in the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V; American Psychiatric Association, 2013), and is marked by an overwhelming fear of an object or situation disproportionate to the actual danger present. There are a number of criteria required to warrant a diagnosis of phobia. Persons suffering from phobia experience intense anxiety immediately upon coming into contact with the feared object or situation, which may lead to panic attacks. The feared object or situation is either endured with extreme fear or actively avoided. Active avoidance of the fear interferes in the person's daily life, causing distress and disruption in everyday activities. Phobic persons, for instance, may take a longer route to work every day specifically to avoid encountering their fear, or refuse an apartment in a certain area of town. If, however, someone has a strong fear of a certain object (e.g. snakes), but does not encounter it in their daily life, this would not classify as a phobia. To be diagnosed with phobia, the fear must last a minimum of six months and the symptoms exhibited must not be explainable by any other mental disorder.

There are three types of phobia: specific phobia, social phobia, and agoraphobia. Specific phobia refers to fears of specific objects or situations belonging to one of five categories. The first category is animal and common examples of phobias are spiders, snakes, or dogs. The second category is natural environment and incorporates phenomena such as storms, heights, and water. The third category is blood–injection–injury (BII) and includes fears of needles and invasive medical procedures. The fourth category is situational and examples include being on airplanes, in elevators, or in enclosed spaces. The fifth and final category is simply labeled "other," and includes fears of vomiting or choking, contracting an illness, and costumed characters such as clowns.

Specific phobia is one of the most common anxiety disorders and it frequently develops in childhood due to a traumatic experience involving the object or situation. This trauma may be direct, or related to the child by a friend or media coverage. Some variation is found

among the subtypes, as situational phobias often develop in late adolescence or early adulthood. Generally, females report twice as many specific phobias than males, however, the ratios among the subtypes may vary. Females and males report an equal ratio with regard to BII phobias, but females report much higher numbers for the animal, natural environment, and situational subtypes. Having one specific phobia increases a person's likelihood for having a second of the same subtype. Persons frequently suffer from two or three phobias at a time.

Social phobia, also known as social anxiety disorder, is a fear of social situations and has two subtypes. Generalized social phobia refers to a fear that extends to most social situations whereas non-generalized social phobia refers to a fear of specific situations such as performing or public speaking. Social phobia is distinct from specific phobia in that the distress that arises is not due to fear of perceived danger, but rather a fear of scrutiny by others. Persons suffering from social phobia fear their own actions or anxiety in social situations will draw attention and negative evaluations (e.g. "they will think I'm boring, stupid, or unlikeable"). Common anxious behaviors in social situations include trembling, blushing, sweating, difficulty speaking, and staring. Because social phobia is often comorbid with other anxiety disorders, depressive disorder, or substance use disorders, an individual's anxious symptoms must be found to be independent of other medical conditions to warrant a diagnosis of social phobia.

Social phobia develops slowly over time, beginning in a childhood marked by shyness or social inhibition. The phobia reaches its peak in adolescence and its effects are often lifelong if not treated. The phobia may diminish over time only to resurface during a later life change (e.g. divorce or a new job). Females report experiencing social phobia up to twice as much as males.

Agoraphobia is a distinct form of phobia prevalent in individuals who suffer from recurrent and unexpected panic attacks, and/or panic disorder. Agoraphobic persons fear going out into public places where they will be unable to escape or receive help in the event of a panic attack. Unlike situational phobia, the fear is not due to the danger of the situation itself, but rather the potential social consequences of having an unexpected attack in public. No specific stimuli trigger the panic attacks, and even when the agoraphobic individual is removed from the public space, they experience heightened anxiety in the anticipation of the next attack. To receive a diagnosis of agoraphobia, individuals must fear entering into two or more of the following public situations: using public transportation, being in open spaces, being in enclosed spaces, being in a crowd, or being outside the home alone. Agoraphobia typically develops in late adolescence or early adulthood, and it afflicts females twice as much as males.

Adult persons suffering from any phobia recognize that their fear is disproportionate to the actual danger present; however, children have more difficulty in determining the feared object or situation is not actually a threat. Their fears are often more transient, changing frequently and making it more difficult to provide a definite diagnosis for those under 18 years old. To receive a diagnosis of phobia, children must exhibit the fear for at least six months. Additionally, children suffering from social phobia must exhibit the fear not only among adults, but also peers their own age. Children with social phobia are able to maintain normal relationships with familiar people, but become anxious at the thought of other social situations.

Related Psychological Disorders

Several other mental disorders share similarities with phobia and should be considered when attempting to make a diagnosis. Post-traumatic stress disorder (PTSD) bears several similarities to phobia, especially as they both often develop after a traumatic event and involve fears of triggering stimuli. There are more criteria to be met for a diagnosis of PTSD, however, and if an individual's symptoms fall short, specific phobia should then be considered.

Other distinct disorders include separation anxiety (fearing a particular situation due to the possibility of being separated from a primary caregiver), obsessive–compulsive disorder (fearing an object or situation because of obsessive thoughts), hypochondria (obsessing about bodily symptoms or contracting serious illnesses as opposed to the stimuli that may lead to the illness), and eating disorders (fear that is limited to consuming certain foods). Several psychotic disorders such as schizophrenia can also cause individuals to suffer anxiety and fear, though the source of these fears is within their own delusions and not outside triggers.

Social phobia and depression both involve an avoidance of social situations, but for different reasons. In depression, the avoidance is due to a lack of interest in socializing whereas persons suffering from social phobia actively avoid social situations, fearing the evaluations of others.

Cultural differences are important to take into consideration when diagnosing social phobia. Different forms of verbal and nonverbal communication may reflect shyness in one country and respect in another (e.g. personal space or eye contact). Social anxiety disorder also shares some similarities to a Japanese phenomenon known as "taijin kyofusho" which is characterized by a fear of offending others with your actions as opposed to a fear of being personally evaluated.

Assessment and Treatment

Phobias are most accurately diagnosed through a multi-modal method. Oftentimes, patients fill out self-report measures assessing their fears before they meet with a clinician one on one. The clinician conducts a structured or semi-structured interview accompanied by a behavioral assessment. In the behavioral assessment, the patient is exposed to their fear and the clinician determines its nature and severity. The clinician makes note of the intensity of fear experienced by the patient, specific cues that change the intensity (e.g. color, size, movement, etc.), physical sensations experienced (e.g. palpitations, dizziness, etc.), cognitive anxieties (e.g. "it will bite me"; "people will think I'm stupid"), and behaviors aimed to escape, avoid, or distract from the object or situation. Behavioral assessment is an important part of a clinician's assessment since self-report measures are not always entirely accurate. Patients often have difficulty recalling cues that affect the intensity of their fear and they also frequently overestimate the fear they experience.

Once an assessment is completed, the clinician will reach a diagnosis and rule out any alternative diagnoses. Furthermore, baseline data collected will inform clinicians as to the severity and frequency of symptoms and associated problems. From this, specific problems will be targeted for treatment. If a patient has already received some form of treatment, the

assessment will also determine how effective said treatment was and if the patient has experienced any relapse.

Individualized treatment strategies are planned for each patient. Treatment of specific phobia has been shown to be very effective and cause lasting improvement with as little as one session. Social phobia and agoraphobia are likewise responsive to treatment, though may require more sessions to see significant effects. Cognitive behavioral interventions are the most effective therapy strategies for all three types of phobia and exposure therapy is considered the first-line treatment. Exposure therapy involves exposing the patient to their fear in increments, starting with an easy task (e.g. looking at a picture of their feared animal) and gradually exposing them to more and more challenging tasks (e.g. being in the same room with the animal; touching the animal). The patient works their way up this fear and avoidance hierarchy, becoming comfortable at each new level before conquering the next level of exposure. When exposure scenarios are difficult to arrange, clinicians often set up a virtual reality whereby the feared situation is simulated in a three-dimensional space using various sensory technologies and props to stand in for the real objects.

To supplement exposure-based therapies, there are several other treatments shown to help persons with phobias. One such treatment is muscle relaxation techniques. These techniques are often taught in an attempt to calm physiological arousal in the presence of anxiety-provoking stimuli. In contrast, muscle tension techniques are taught to individuals suffering from the BII phobia, where the sight of blood or injections often leads to fainting. Patients are instructed to tense their muscles when encountering their feared stimuli. This elevates their blood pressure which in turn prevents them from losing consciousness. Finally, cognitive restructuring is a treatment whereby patients learn to challenge instinctual beliefs and predictions about their fears and examine evidence for any truth therein.

In addition to the above strategies, treatment for social phobia includes social skills training. Patients are given instruction on improving conversation and social skills, including maintaining eye contact, initiating conversation, and reading non-verbal communication. These new skills are employed in role-play exercises and gradual initiations into social interactions.

Pharmacological treatments have also been found to be effective for social phobia and agoraphobia, most notably selective serotonin reuptake inhibitors (SSRIs). Pharmacotherapy and CBT have been found to be equivalent in their effectiveness, however, the former is usually only prescribed to individuals not interested in the latter.

Positive Self-capital

Laura Borgogni[1] and Mariella Miraglia[2]

[1] *Sapienza University of Rome*
[2] *University of Liverpool*

Positive self-capital refers to the set of the positive features of individual functioning, which is able to support individuals' health and well-being as well as to uncover their potentialities and abilities, enhancing successful performances and personal development.

The interest in these positive characteristics has flourished over recent decades in line with the emergence of a new stream of theoretical and empirical research, known as positive psychology, led by the psychologist Martin Seligman. The attention shifted to the forgotten missions of helping healthy people to actualize their human potential, and the focus was on individuals' strengths, happiness, well-being, growth and self-achievement as opposed to the negative perspective centered on weakness, mental illness, and dysfunctional behaviors (Seligman, 2002). The positive psychology movement rapidly expanded in the organizational domain, due to its emphasis on individual core competencies associated with elevated performance and on individual talents, essential for the long-term competitive advantage of contemporaneous organizations. More specifically, two parallel approaches developed, commonly referred to as positive organizational scholarship (POS; Cameron, Dutton, & Quinn, 2003) and positive organizational behavior (POB; Luthans, 2003). The focus's width is what differentiates the two perspectives: POS relies on the macro, organizational level, while POB aims at the micro, individual level. Moreover, POB set a series of criteria to define the psychological strengths or capacities of positive self-capital. The criteria state that psychological strengths/capacities have to be positive, relatively unique to the field of organizational behavior, theory- and research-based, measurable, state-like (i.e. developable), and associated with performance outcomes.

Within this approach, Luthans and colleagues (Luthans, Youssef, & Avolio, 2007) proposed the concept of *psychological capital* (PsyCap), which refers to a high-order construct, synergistically integrating some assets of positive self-capital. PsyCap designs "an individual's positive psychological state of development" (Luthans et al., 2007, p. 3), characterized by a set of individual positive features which favor person-organization fit, higher performance, and personal and professional growth stemming from experience, difficulties, and errors.

The construct goes beyond the concepts of human capital (i.e. "what you know") and social capital (i.e. "who you know"). It depicts the psychological self, which includes not only "who you are" but also "who you can become," acknowledging the possibility of development from the actual to the potential self and recognizing the state-like nature of PsyCap, relatively malleable and open to change (Luthans et al., 2007). Four sub-dimensions make up the PsyCap higher-order factor: self-efficacy, optimism, resiliency and hope.

Drawing upon Bandura's extensive work within the social-cognitive theory, self-efficacy refers to the person's confidence in his/her abilities to activate the resources and course of action needed to effectively complete a specific task in a certain context (Bandura, 1997). Self-efficacious individuals set more difficult goals for themselves, are highly self-motivated, perceive obstacles as challenges, increase effort and perseverance to pursue their objectives. As a result, individual growth, job performance, and a series of desirable attitudinal outcomes (e.g., job satisfaction, organizational commitment) are sustained (Bandura, 1997; Stajkovic & Luthans, 1998). More importantly, self-efficacy beliefs may be developed through specific strategies, namely mastery experiences of success, social modeling and vicarious learning, social persuasion and positive feedback, modification of psychological and physiological states (Bandura, 1997).

Based on Seligman's (1998) definition, optimism describes a positive explanatory style that attributes positive events to internal, permanent, and pervasive causes while viewing negative occurrences as external, temporary, and situation-specific. Optimistic individuals take credit for their success and distance themselves from unfavorable situations, internalizing the positive elements of their existence. Consequently, a protection from depression, self-blame and guilt is provided, sustaining positive outcomes such as increased performance in various life domains, including the workplace (Luthans et al., 2007; Seligman, 1998). Aware of the risks that can derive from an unrealistic prediction of events, the PsyCap perspective stresses flexibility and realism as prominent properties of optimism. An optimistic style originates from the individual's appraisal of the situation and his/her self-efficacy beliefs, requiring self-reflection and preventive planning to avoid negative consequences. Also, optimism is susceptible to development through a personal growth process, which aims at activating an optimistic explanatory style by encouraging leniency for the past, appreciation of the present, and flagging positive opportunities for the future (Schneider, 2001).

Founded on Masten's developmental and clinical work (Masten, 1994), resiliency refers to "a developable capacity to rebound or bounce back from adversity, conflict, and failure or even positive events, progress, and increased responsibility" (Luthans et al., 2007, p. 18). The reference to positive events emphasizes that resiliency is a reaction to all those situations perceived by the individual as overwhelming changes. Resiliency works through a dual mechanism, which enables people to preserve and enhance their assets and to simultaneously reduce the risk factors within the individual and his/her environment. This allows them not only to promptly respond to challenges, bounce back, and re-establish the original equilibrium, but also to attain even higher performance levels. As for the other PsyCap dimensions, multiple developmental strategies may be used to boost resiliency in the workplace. Strategies can focus on assets (i.e. by enhancing the actual and perceived level of available resources), on risks (i.e. via risk management techniques that transform the perception of risks in developmental opportunities), and on the entire process, to promote self-awareness (e.g. assets assessment) and self-regulation (e.g., using assets to overcome risks).

Following Snyder's definition (2000), hope designates a positive motivational state based on the interaction of two elements, agency and pathways. Agency (or "willpower") represents a cognitive state, responsible for setting realistic and challenging goals and activating self-guided determination, energy, and control to achieve the goals. Pathways (or "waypower") refer to the individual's capability to generate alternative action paths to accomplish the set objectives, if the original plans are not functional. Hence, hope allows for the creation of a higher number of action strategies, which can lead to successful job performance, greater job satisfaction, and positive leadership (see Luthans et al., 2007). Practical methods, such as goal setting, contingency planning, and re-goaling, have been identified to develop hope in the workplace.

The described PsyCap characteristics could be viewed as an integrated and synergistic set of *personal resources* (Luthans et al., 2007). Originating in the stress literature (Hobfoll, 2002), personal resources depict the personal characteristics activated by the individual in problematic situations or when further psychological resources are needed to achieve a certain objective. Recently, they have been included within the job demands-resources (JDR) model (Bakker, Demerouti, & Sanz-Vergel, 2014) and conceptualized as those individual characteristics associated with resiliency and control over work context, enhancing goal attainment and professional development. Some examples are optimism, self-efficacy, and self-esteem.

A further relevant construct to define positive self-capital is *core self-evaluation*, a neighbor concept of PsyCap, developed by Judge and colleagues (Judge, Erez, Bono, & Thoresen, 2003). Core self-evaluations are the fundamental evaluations that people make about themselves, their overall value and their capabilities. As PsyCap, they represent a broad, latent, higher-order construct, composed of four well-established sub-dimensions within the personality literature: (1) self-esteem, the general evaluation of one's self-value; (2) generalized self-efficacy, overall beliefs of personal efficacy to perform across a variety of situations; (3) neuroticism, the tendency to frequently experience negative emotions (e.g. anxiety, stress, depression) and to focus on the negative aspects of the self; and (4) locus of control, the beliefs about the causes of life events that can be attributed to internal or external factors. High core self-evaluations enhance a positive view of the self across a variety of situations, positively impacting well-being, job satisfaction, and performance. Indeed, individuals see themselves as worthy of respect and regard (high self-esteem), able to achieve their goals (high self-efficacy), in control of the events (internal locus of control), and they are more optimistic and less self-doubting (low neuroticism). The principal difference between core self-evaluations and PsyCap pertains to the trait-like and more general nature of the former. In fact, core self-evaluations describe a set of stable individual characteristics, related to the broader domain of the individual functioning (and not only to the workplace), reflecting the individual's basic appraisal of his/her worthiness, effectiveness, and capability as a person.

The trait-like nature is the same element distinguishing PsyCap from another high-order construct, ascribable to positive self-capital, that is *positivity*. Positivity defines a positive orientation toward life, "a pervasive mode of facing reality, reflecting upon experience, framing events, and processing personal and interpersonal experiences throughout time and across life circumstances" (Caprara & Alessandri, 2014, p. 202). Positivity is a parsimonious and comprehensive concept, a latent dimension, which comprises the triad of life satisfaction, self-esteem, and optimism. Life satisfaction refers to the level of meaningfulness and

gratification the individual acquires from the multiple activities and relationships in the diverse domains of his/her life. Contrary to the PsyCap dimension, optimism is conceptualized as dispositional and describes the propensity to view and expect future events as more positive than negative. Longitudinal research (Alessandri, Caprara, & Tisak, 2012), along with genetic studies (Caprara et al., 2009), has demonstrated that positivity is a basic stable predisposition that accounts for individuals' adjustment and achievement in different life domains, including organizational settings.

With regard to future directions, research may better investigate whether and how positive self-capital can decline over time and which contextual and personal conditions may decrease such loss. This might be particularly worthy for the state-like dimensions of PsyCap, which fluctuate over time, or for personal resources that, according to the conservation of resources theory (Hobfoll, 2002), are defined as vulnerable and subject to depletion.

Moreover, although some evidence upholds the cross-cultural validity of the aforementioned constructs, further studies could better explore to what extent the various subdimensions are influenced by culture and life experience. Furthermore, research may aim at identifying additional positive psychological characteristics to describe positive self-capital. For example, Luthans et al. (2007) listed a series of supplementary potential constituencies of PsyCap, such as creativity, wisdom, flow, humor, and authenticity. Finally, a challenge for researchers, practitioners, and health psychologists would be to design and test interventions and practices able to strengthen the characteristics underlying positive self-capital as powerful determinants of individuals' enrichment and flourishing.

Psychopathy

Samantha Chen and Rachel A. Plouffe

University of Western Ontario

Conceptualization of Psychopathy

As early as the twentieth century, psychopathy was studied by researchers and clinicians among forensic populations as a clinical syndrome. Prior to the twentieth century, there existed no agreed upon operational definition of the construct, which made any diagnosis of psychopathic tendencies difficult. However, psychopathy has emerged as a methodically and explicitly distinct construct that is defined by a constellation of interpersonal, affective, and behavioral characteristics. In general, psychopathic individuals display an interpersonal style characterized by grandiosity, dominance, arrogance, egocentricity, manipulation, and deceitfulness; a behavioral style characterized by impulsivity, irresponsibility, poor behavioral controls, and a proneness to violate social and legal norms and expectations; and an affective experience characterized by shallow or deficient affect, diminished capacity for empathy, guilt, or remorse, callousness, and an inability to form strong emotional bonds with others.

Most modern conceptions of psychopathy are derived from the work of psychiatrist Hervey Cleckley whose seminal book, *The Mask of Sanity* (1976), has strongly influenced empirical investigations of psychopathy. Based on a series of clinical case studies, Cleckley identified 16 qualities that exemplify the disorder such as grandiosity, arrogance, callousness, superficiality, and manipulativeness. Robert Hare is credited with the first formal operationalization of Cleckley's concept of psychopathy: the Psychopathy Checklist and the subsequent revised version, the Psychopathy Checklist-Revised (PCL-R). The PCL-R is the most widely validated and accepted diagnostic instrument for assessing psychopathy among numerous clinical and forensic populations. It is composed of 20 items and is traditionally viewed as having a two-factor solution. Factor 1 consists of personality traits such as glibness/superficial charm, a grandiose sense of self-worth, pathological lying, conning/manipulativeness, lack of remorse or guilt, shallow affect, callousness/lack of empathy, and failure to accept responsibility for actions. Factor 2 traits reflect more behavioral characteristics such as a parasitic lifestyle, poor behavioral controls, early behavioral problems, lack of realistic/long term goals, impulsivity,

irresponsibility, juvenile delinquency, revocation of conditional release, and need for stimulation/proneness to boredom.

Psychopathy, sociopathy, and antisocial personality disorder have often been used synonymously to describe the same disorder; however, these terms describe distinct conditions that should be differentiated. Antisocial personality disorder places emphasis on antisocial and criminal behavior, whereas psychopathy and sociopathy are considered dispositional conditions that primarily emphasize affective and interpersonal characteristics.

Although psychopathy is generally treated as a unitary construct, a number of variants have emerged from the growing body of research and theory. The classic distinction has been made between primary and secondary psychopathy. Primary psychopathy is theorized to reflect a heritable, biologically acquired affective and interpersonal deficit. These individuals tend to be confident, dominant, and free from negative emotions. Secondary psychopaths, often referred to as sociopaths, are conceptualized as having acquired, affective disturbances resulting from early socialization forces or arising indirectly as a means of coping with environmental stressors. The manipulative and callous traits present in secondary psychopathy represent a more psychopathological, hostile, and violent variant, and are typically accompanied by emotional dysregulation.

Recently, a triarchic conceptualization of psychopathy has been proposed in terms of three broad, phenotypic constructs: disinhibition, boldness, and meanness. Disinhibition entails proneness toward impulse-control problems, including lack of planfulness, reactive angry emotionality, insistence on immediate gratification, and deficient behavioral restraint. Boldness represents a propensity toward social dominance, thrill-seeking, and low stress-reactivity. Meanness describes a constellation of attributes including deficient empathy, inability to form close attachments with others, exploitativeness, and empowerment through cruelty.

Psychopathy and Personality

Theorists and researchers have more recently contended that if psychopathy exists as a personality trait among clinical populations, it should also present in the general, nonclinical population. Not all individuals who display psychopathic characteristics come into contact with the justice system, but they still may demonstrate the same socially aversive tendencies as the psychopathic criminal. Similar to core personality constructs such as the Big Five traits, levels of subclinical psychopathy exist dimensionally, where one end of the continuum represents individuals exhibiting low levels of psychopathy, and the other end represents individuals with many psychopathic, socially aversive tendencies. Approximately 1% of the general population exhibits psychopathic tendencies, whereas 15–25% of offender populations possess these characteristics. Currently, the predominant method for assessing subclinical psychopathy is the Self-Report Psychopathy scale (SRP-III). The SRP-III was modeled after the PCL-R and reflects its underlying structure. Specifically, the SRP-III consists of four subscales: Interpersonal Manipulation, Callous Affect, Erratic Lifestyle, and Antisocial Behavior.

Subclinical psychopathy is closely related to Machiavellianism and subclinical narcissism. The three unique traits are collectively known as the Dark Triad of personality due to their common correlates. For instance, each trait is linked to low agreeableness. This is in

keeping with the notion that individuals low in agreeableness tend to be selfish, stubborn, outspoken, aggressive, impatient, and intolerant.

Subclinical psychopathy is characterized by low levels of agreeableness, conscientiousness and honesty-humility. In undergraduate student samples, psychopathy has been related to instances of plagiarism and cheating in school, as well as low GPA. Psychopathy has also been related to such variables as a need for competition, low co-operation, low goal setting, and short-term mating tactics.

Psychopathy and Psychopathology

The relations between psychopathy and psychopathology have been well established. There has been considerable research on the diagnostic co-occurrence of psychopathy with antisocial personality disorder (APD). Findings generally suggest that most cases of psychopathy diagnosed within forensic settings will meet the diagnostic criteria for APD, but only half or fewer of the cases of APD will meet criteria for psychopathy. In addition, criterion sets for APD from the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and psychopathy from the PCL-R are relatively similar, albeit alternative, efforts at identifying the same personality disorder. However, the DSM criteria for APD place more emphasis on delinquent, criminal, and irresponsible behaviors than the PCL-R criterion set for psychopathy.

Psychopathy is often reported to be comorbid with narcissistic personality disorder (NPD). Some features of NPD are explicitly suggestive of psychopathy, notably a grandiose sense of self-importance and arrogance, lack of empathy, and being unwilling to recognize or identify with the feelings and needs of others, and interpersonal exploitation.

The relationship of psychopathy with anxiety disorders has been controversial. Cleckley included within his original criteria for psychopathy an absence of anxiety. In contrast, the DSM states that APD is associated with anxiety disorders, which may be attributable in part to the limitation of many of the APD studies being conducted with clinical populations. However, increased prevalence rates of panic disorder, agoraphobia, and social phobia have been reported among individuals diagnosed with APD.

Psychopathic individuals are also involved in various forms of high-risk behaviors. Psychopathy has been consistently related to elevated rates of substance use, gambling, and other disorders of impulse control. APD has been shown to provide a significant risk for drug and alcohol use. It has been suggested that APD, psychopathy, and substance-related disorders may share a common underlying psychopathology of disinhibitory temperament. Many twin studies have suggested a common genetic contribution to APD and substance use disorders.

Furthermore, research based on the two factors that emerge from the PCL-R has shown unique relationships with psychopathology. Individuals scoring high on Factor 1 (i.e. narcissism and callous-unemotional traits) tend to present as more psychologically adjusted than those who score high on Factor 2 (i.e. impulsive/antisocial characteristics). High Factor 1 scores are related to decreased stress and anxiety, lack of reported psychiatric symptoms, and greater ability to cope. In contrast, high scores on Factor 2 are related to increased stress and anxiety, neuroticism, and difficulty coping with everyday stressors. Furthermore, individuals scoring high on Factor 1 also demonstrate lower levels of substance abuse, fewer symptoms of PTSD, and decreased risk for suicide than individuals who score high on Factor 2.

Etiology of Psychopathy

A number of physiological, genetic, and developmental theories have been proposed to explain the etiology of psychopathy. There is not a single, overarching theory that explains why psychopathy develops in some individuals and not others, but it is generally accepted that nature and nurture interact to produce behavioral events and characteristics aligned with psychopathy. For instance, it has been demonstrated that approximately 50% of individual differences in psychopathic traits are attributable to genetic factors, but these genetic factors interact with the environment to influence one's personality structure. Although no specific "psychopathy gene" has been identified, it is generally accepted that a number of genes contribute to the disorder.

Cortical regions associated with the presence of psychopathic characteristics include the limbic system, the septo-hippocampal-orbital frontal system, and the amygdala. It has been proposed that psychopathy is associated with circuitry or mechanistic issues within these brain regions. Specifically, cortical excitability is lowered, and information that would, under normal circumstances, produce stress in an individual does not have the same effect on individuals with psychopathy.

One theory that has been proposed regarding the development of psychopathy is the response modulation hypothesis, which describes the cortical dysfunction of psychopathic individuals. According to this hypothesis, psychopaths engage in behaviors that they have previously been rewarded for regardless of possible punishment due to an inability to focus their attention on secondary information. Such secondary information can include possible consequences for their actions, implicit rules of conduct, or learned associations. A second hypothesis, the violence inhibition mechanism (VIM) hypothesis, contends that a deficit in the amygdala causes a failure in conditioned emotional responses, and this, in turn, causes a failure to develop a sense of morality. For instance, in normal individuals, distress of a victim activates the VIM and increases situational empathy. However, the VIM is not activated in psychopathic individuals due to these amygdalar deficits.

A variety of environmental antecedents to psychopathy have also been proposed as risk factors for the development of psychopathic characteristics. Early life risk factors for psychopathy include being physically abused by parents, maternal psychopathy, hyperactivity-impulsivity problems, and parental deviance. These environmental factors are not necessarily causal mechanisms of psychopathy, but rather, they are predictive of the development of the disorder later in life.

Clinical Implications

A large number of studies have shown that the presence of psychopathic features is associated with a propensity for aggression and violent behavior in childhood, adolescence, and adulthood. Furthermore, psychopathy is one of the strongest predictors of future criminal conduct and violent recidivism in both criminal offenders and psychiatric patients.

Research has also established a relation between psychopathy and sexual coercion against women. In terms of prevalence, psychopaths appear to be more likely than non-psychopathic criminals to rape. In addition, psychopaths are overrepresented in samples of sexual offenders

and appear to constitute a coherent subgroup of rapists. Moreover, the impulsive-antisocial deviance component of psychopathy has been found to predict subsequent sexually aggressive behavior in convicted offenders. The components of psychopathy have also been demonstrated to predict sexually coercive behavior against women in non-criminal samples.

Clinical and forensic interest in psychopathy also involves the implications for treatment amenability. Therapeutic pessimism about psychopathy has been so engrained among clinicians and researchers that it is rarely subjected to empirical evaluation. Of those that have been conducted, most have had serious methodological flaws, such as the lack of randomized controlled trials, difficulty with reliably measuring treatment outcomes, and the lack of treatment programs developed specifically for those with psychopathy. Furthermore, psychopathic traits tend to be associated with low treatment motivation and poorer treatment response.

A recent review of the literature reported that treatment results for adult psychopaths range from low-moderate to poor. However, a small body of quasi-experimental evidence challenges the assumption that individuals with psychopathy do not respond to conventional treatment. For example, a meta-analysis of 42 studies indicated that across treatment modalities, psychotherapy was moderately successful in reducing recidivism for psychopathic individuals (on average, a 62% success rate). Furthermore, a study of 871 civil psychiatric patients indicated that individuals with psychopathic tendencies who received intensive treatment during one 10-week period appeared just as likely to benefit from treatment as nonpsychopathic patients, in terms of reduced violence potential. Randomized controlled trials are necessary in order to draw causal conclusions regarding treatment efficacy for psychopathic tendencies.

Religiosity

Paul F. Tremblay

University of Western Ontario

Religiosity Conceptualized

If we gave people a survey asking them about the extent of their religiosity, we might assume that most of them would understand the question. We would find variation in the responses with some people reporting that they are not at all religious, some reporting that religion plays a central role in their life, and others reporting no formal connection with a specific religion but that they see themselves as spiritual. At the same time, many people might question exactly what we mean by religiosity. Although religion and spirituality, and the difference between the two, can be difficult to define, researchers who study the psychology of religion generally converge on the view that both terms refer to a search for the sacred or for transcendence. In religion, the search occurs within an organized set of shared beliefs, doctrines, and rituals, whereas in spirituality, the search occurs more on a personal level often with less formal direction. The term "sacred" can refer to the divine, a higher power, God, or to abstract concepts such as truth, good, and beauty. Transcendence literally means "to go beyond the world" or "beyond oneself." A similar phenomenon in psychology is the peak experience proposed by Maslow, consisting of a euphoric or ecstatic state in which a person may experience a greater sense of unity with the universe and a loss of a separate sense of self or time.

Religion as a Unique Phenomenon

Another challenging conceptual issue is whether religion represents a unitary phenomenon not reducible to more fundamental psychological, social, or physical dimensions. Paloutzian and Park (2013) present a critical examination of religion, questioning whether it is a distinct psychological phenomenon. They argue that religion may belong to a larger psychological domain of a need that people have to make meaning. They also question the idea proposed by Pargament (1992) that the distinctiveness of religion lies in the search for the sacred. They argue that sacred objects are arbitrarily defined as such by people and that

the need for transcendence, also proposed by Pargament, may be reducible to more basic psychological needs. In a sense these questions are similar to whether art can be reduced to more basic psychological or even biological processes. Concepts such as art, religion, money, and justice can certainly be studied at more elementary levels of explanation, whether physical, chemical, or genetic. However, at issue is the extent to which the concept that is proposed loses its essence when subjected to reductionism. Regardless of the validity of the sacred, the divine, or transcendence, it seems clear that since the dawn of consciousness, humans have longed for something that they cannot explain. In the words of St. Augustine, in his *Confessions*, "Thou hast made us for thyself, and our heart is restless until it finds its rest in thee."

Religiosity

Saroglou (2014) defines religiousness (or religiosity) as "the individual differences on being interested in and/or involved with religion. This includes individual differences in attitudes, cognitions, emotions, and/or behavior that refer to what people consider as a transcendent entity" (p. 5). He adds that religiousness can be thought of as including four dimensions: believing, bonding, behaving, and belonging. As part of a meta-analysis on religiosity and personality, Saroglou (2010) also categorized the various measures of religiosity used in various studies as: (1) Religiosity involving beliefs and practices in relation to a transcendent being within an established tradition or group; (2) Spirituality or mature faith that includes critical consideration of beliefs independent of religious groups; and (3) Fundamentalism consisting of authoritarian and dogmatic beliefs and practices. An earlier distinction between intrinsic and extrinsic forms of religiosity was proposed by Gordon Allport in the 1950s. The intrinsic dimension involves seeking the sacred and transcendent for its own sake, whereas the extrinsic dimension involves external motives or rewards such as affiliation and becoming a respected member of society. Allport viewed the two dimensions as fairly independent of each other, and he proposed that intrinsic religion was the healthier form. Some aspects of religiosity, however, do not fall clearly within the intrinsic or extrinsic domain. For example, affiliation may be considered extrinsic but also have intrinsic properties when thought of as communion.

Universality and Individual Differences in Religiosity

Personality researchers investigate the underlying psychological structure of humans, the individual differences in psychological dimensions, the factors that account for the variation across individuals, and the outcomes or consequences of this variation. Religion is indeed a universal phenomenon part of the human experience, not unlike other universal phenomena such as music, art, and literature. The landscapes of many cities across the world display majestic architectural testaments to the universal reality of religion and spirituality. At the same time, these landscapes do not show the wide range of individual differences in religiosity, from those at one end of the continuum who define themselves as atheistic or even anti-religious, and those at the other end who live behind the cloistered walls of monasteries, dedicating themselves entirely to their religion. Most people fit within those boundaries.

In fact, researchers use various self-report questionnaires to assess where people fit on a continuum of various religiosity aspects such as general religious or spiritual attitudes, religious coping, attachment to God, doubt, mystical experiences, and the use of prayer.

Distinction Between Religiosity and Personality Traits

Religiosity does not fall within the category of fundamental personality traits, in part because it has a belief component, which is not characteristic of traits (Ashton & Lee, 2014). Instead, religiosity is sometimes referred to as a characteristic adaptation that develops throughout the course of life largely under the influence of socialization within a culture and individual experiences. This is not to say that religiosity cannot be conceptualized as a stable individual difference. In fact, research has shown that religiosity is fairly stable, in terms of rank-order, across the lifespan, meaning that within a group or population, people who were the most religious when they were young are likely to be among the most religious also at a later age. At the same time, people can still go through changes such as experiencing conversions or abandoning their religious practice or beliefs. Also longitudinal research has shown that religiosity tends to decrease during the transition from adolescence to adulthood.

Religiosity also differs from personality traits in terms of personal agency. Although people are somewhat bound by their personality traits, they are also self-determined motivated agents that make choices, set goals and develop long-term projects. Notwithstanding the early constraints of their particular social and cultural milieu, young people experience increased freedom in defining their attitudes, beliefs, and values as they live through adolescence and emerging adulthood.

People also vary in religiosity as a result of their life experiences. High levels of religiosity might be reinforced by early experiences, including positive influences of religious or spiritual role models. Religious people may find it easy to derive positive emotions from religious activities such as participating in choirs, leading discussion groups, or camp events, especially if these activities provide opportunities to discover and improve their talents. People have also benefited from religiosity as a coping mechanism.

Association Between Religiosity and Personality Variables

Ashton and Lee (2014) reviewed the associations between religiosity and personality traits based on a meta-analysis by Saroglou (2010) and additional research using their HEXACO model of personality, a model related to the five-factor model that includes an additional dimension of honesty-humility. They reported that Agreeableness and Conscientiousness correlated modestly with the three types of religiosity measures, and that Honesty-Humility correlated with religious measures typical of the Religiosity category outlined by Saroglou. Openness to Experience was modestly correlated with measures of spirituality and a questioning faith but negatively with fundamentalism. In their review Ashton and Lee considered the possibility that the associations between religiosity and personality variables could result from socially desirable responding but pointed out that research based on observer reports of teachers and parents revealed similar findings.

Biological Bases of Religiosity

Although a number of popular books have proposed a God gene or that the brain is wired for God, research on biological substrates of religiosity need to consider the likelihood that personality traits are mediating mechanisms (Ashton & Lee, 2014). Behavioral genetic research has revealed that religiosity has a heritable component similar to that of personality traits. However, that genetic influence is probably pointing to more fundamental personality traits such as conscientiousness and agreeableness. Heritability is small in adolescence and increases in adulthood to levels similar to the heritability of personality traits. This increase can be explained by the fact that adults have more freedom than adolescents in choosing their environment and practice or absence of religious activities. Although some researchers in evolutionary psychology view religion as a direct product or adaptation of evolution by natural selection, a consensus seems to be emerging that in addition to its cultural evolution, religion can also be seen as a byproduct of other non-religious psychological mechanisms designed by natural selection.

Future Directions

Research Methods

Nomothetic research focuses on basic principles that apply to everyone, whereas idiographic research focuses on unique aspects of individuals. Allport was a firm advocate of the need for idiographic research in the study of personality. The study of individual cases (e.g. saints, presidents, mass-murderers, or ordinary people) seems particularly appropriate for understanding the various forms and motives for religiosity. Other qualitative methods including unstructured interviews and ethnographic studies can uncover religious phenomena that would otherwise remain undetectable. Personality researchers have incorporated narratives as data collection procedures to study how people make meaning of their life through the stories they generate. Meaning making consists of making sense out of ambiguity, the unknown, chaos, losses, or crises in life. In terms of nomothetic research, future studies can incorporate advancements in psychometrics to develop improved measures of various aspects of religiosity (across cultures and religious groups) and intensive longitudinal analytic methods to investigate diary data of how people practice religiosity.

Evolving Ideas and the Role of Personality Research

Theologies and ideas about the sacred and transcendence evolve with the accumulation of knowledge. Some theological ideas (e.g. ground of being, an ultimate reality, or the source of moral order) are more compatible with scientific and philosophical knowledge than those describing God with anthropomorphic metaphors. Ultimate questions about our place in the universe, being itself, how we should live, and the nature of reality are not the sole property of any one discipline. Psychology has a major role to play in furthering our knowledge of consciousness, free will, and self-control. These psychological/philosophical dimensions may have important theoretical connections to religion and

spirituality. In personality psychology, although we have made great strides in mapping the fundamental personality variables and characteristic adaptations, much of our human complexity remains open to further exploration.

Risk Taking

Clara S. Lee and Joshua S. Bourdage

University of Calgary

Risk taking is defined as the engagement in behaviors that are associated with some probability of undesirable results. Prototypical risky behaviors could include criminal behaviors, dangerous driving, drug use, and alcohol consumption. Although sensation seeking has been a consistent correlate of risky behaviors, risk taking is a separate construct from sensation seeking. Instead, those high on sensation seeking are defined by their search for novel sensations, driven by a desire for complexity and intensity. Nonetheless, such experiences often come packaged with risks, whether it be physical, social, legal, or financial. Typically, these risks are less likely to deter sensation seekers who often think the benefits of such sensations outweigh the risks.

Sensation-seeking has been correlated with many of the prototypical risk taking behaviors mentioned previously, such as smoking, drug use, and dangerous driving. Interestingly, not all types of risky behaviors engaged in by sensation seekers are destructive – rather, sensation seekers also tend to be drawn toward prosocial risk taking behavior. For instance, those high in sensation-seeking may be drawn to dangerous but prosocial vocations such as firefighting and policing. In terms of interests, those high in sensation seeking may pursue sports involving higher risk, such as skydiving and downhill skiing.

It must be noted that not all sensation experiences involve risk. Novel and complex music and art, in line with a non-conforming general lifestyle, are also sought by some sensation seekers, describing the Experience Seeking factor of sensation seeking. Other dimensions of sensation seeking include Thrill and Adventure Seeking, characterized by the aforementioned physical activities that provide novel sensations and moderate risk such as skydiving and mountain climbing; disinhibition, which refers to seeking sensation through a hedonistic lifestyle, involving drinking, partying, and sex; and Boredom Susceptibility, representing an aversion and restlessness in response to monotony.

Four Perspectives for Understanding Risk taking/Sensation Seeking

Classic debates in the theory of risk taking and decision making theorized that individuals abide by the universal rule of maximizing utility, where possible gains are maximized through necessary risks, by behaving rationally. However, it has been subsequently found that humans do not act rationally at all times, often relying on instincts and heuristics. The Prospect Theory was proposed in 1979 by Daniel Kahneman and Amos Tversky, which earned the Nobel Prize. The theory is commonly cited in the effort to understand risk taking, where tendencies stray toward risk-averse for potential gains, but risk-seeking to avoid potential losses, even when the outcomes are identical. In other efforts to understand risk taking from a cognition standpoint, cognitive processes of adolescents have been examined. It has been proposed that adolescents tend to be more cognitively egocentric, and therefore think of themselves as more invulnerable to undesirable risk outcomes than adults do.

Decision making and risk taking have also been tackled from an emotional standpoint, with the Somatic Marker Hypothesis (SMH). The SMH proposes that emotional responses to positive and negative consequences influence decision making in risky and uncertain situations. These findings have been informed by studies using the Iowa Gambling Task, where it has been found that adult participants who are cognitively adept, yet emotionally impaired, perform worse and take unnecessary risks in the gambling task than normal adult participants. This points toward some role of affect and emotion in guiding decision making.

In addition to the SMH, affective decision making can also be influenced by impulsivity, which in the context of emotional decision making is the inability to inhibit primary responses while attempting to make more calculated decisions. Impulsivity can also be construed as the inability to delay gratification or to self-regulate, which has been theorized by the Self-Regulation Model (SRM) to contribute to risky behaviors as rational decision-making processes are bypassed.

Neuroscientific methods have also been utilized when examining risk taking, contributing to the finding that the frontal lobes are integral in the cognitive analysis of risk. Indeed, damage to the frontal lobes has been found to result in impairment of tasks involving the calculation of risk. Subsequent work using fMRI technology has found specific patterns of neural region activation that corresponds with the selection and anticipation phases of a risk taking task. Biochemistry has also been examined in the psychobiological perspective of the development of risk taking. It was found that decreased monoamine oxidase (MAO), which regulates neurotransmitters, and increased sex hormones, such as testosterone, were associated with high sensation seekers.

Finally, social development perspectives have also been consulted when investigating the development of risk taking. The majority of research has looked into relationships with parents, as well as peers. First, findings indicate that authoritative (high warmth, high discipline) and authoritarian (low warmth, high discipline) parenting approaches result in lower levels of prototypical risky behaviors, as opposed to indulgent (high warmth, low discipline) and neglectful (low warmth, low discipline) parenting approaches. Eventually, peers become more of an influence on adolescents as opposed to parents. It has been consistently demonstrated that those who associate with peers that engage in risky behavior are themselves more

likely to engage in risky behaviors. However, one potential explanation for this is that children and adolescents select peers who have similar interests and tendencies (i.e. risk taking inclinations) rather than that they are influenced by their peers to heightened risk taking.

Experimental risk taking behaviors in adolescents may seem trivial compared to those in adults. However, in regards to sensation seeking, abuse or dependence on addictive substances, such as alcohol or drugs, in adulthood may result from initial sensation seeking tendencies simply for the purpose of novel experiences. It has been found that high sensation seekers are likely to experiment at a younger age, as well as sample more types of drugs, as opposed to low sensation seekers.

Sensation seeking has been correlated with many different groups of risky behavior. These include risky driving, sports, and vocations, as well as substance use, risky sexual behavior, and criminal acts. Generally, it has been found that high sensation seekers are more likely to engage in these behaviors, although different dimensions of sensation seeking are involved in different risky behaviors. For instance, it was found that high scores in Thrill and Adventure Seeking were not as associated with the use of hard drugs as high scores in Boredom Susceptibility and Experience Seeking, presumably to protect their health for the sake of their involvement in extreme sports.

With its important predictive power, there have been debates as to whether sensation seeking and risk taking constitute an important personality dimension on their own and consequently lie beyond the Five Factor Model (FFM) of personality, or whether they are encompassed by the FFM since they share a substantial amount of variance. Both risk taking and sensation-seeking are positively associated with Openness to Experience and Extraversion (r=0.2–0.6), negatively associated with Conscientiousness and Agreeableness (r=0.1–0.5), and not related to Neuroticism.

Current Research on Risk Taking and Sensation Seeking

With the advent of the more recent HEXACO personality model, the associations of risk taking and sensation seeking with personality dimensions justify another look. The HEXACO model differs from the FFM with the inclusion of the Honesty-Humility dimension, as well as the reorganization of the irritability and fearfulness facets. These facets are included in the Neuroticism dimension of the FFM, but belong respectively to the Agreeableness and Emotionality dimensions of the HEXACO model respectively. Once again, the HEXACO model encompasses a significant portion of risk taking and sensation seeking, being positively related to Openness to Experience and Extraversion (r = 0.40–0.45) and negatively related to Honesty-Humility, Emotionality, and Conscientiousness (r = 0.22–0.35). Honesty-Humility provides an important addition to the explanation of risk taking and sensation seeking, especially since individuals lower in levels of Greed Avoidance and Fairness, two of the facets of Honesty-Humility, demonstrate greater risk taking.

While preliminary evidence suggests that adolescents are cognitively egocentric and think of themselves as invulnerable, current research finds few differences between adolescents and adults in the evaluations of inherent risks and seriousness of consequences in a wide range of dangerous behaviors. Instead, it has been theorized that risk taking is a product of both logical reasoning and psychosocial factors. Whereas logical reasoning seems

completely developed by the age of 15, psychosocial factors, which account for more instinctual factors like impulse control, delay gratification, and emotion regulation, continue to develop well into adulthood. As such, developing psychosocial factors may compromise otherwise competent decision making. This has been supported by neuroscientific methods with the socioemotional network, which is sensitive to social and emotional stimuli. This network shows greater activation during risk taking with adolescents, especially in the presence of peers, than the cognitive-control network, which is associated with executive functions, such as planning, and self-regulation. Over time, it seems that the cognitive-control network matures even more with the development of cross-talk across brain regions, finessing response inhibition, quelling the socioemotional network.

The above-mentioned theory belongs to the category of dual-process theories, where it is theorized that people are capable of controlled, analytic processes, but also rely on more instinctive, heuristic processes. It is thought that the latter processes are responsible for risk taking. Also belonging to this group of theories is the fuzzy trace theory, which describes two processes for reasoning about risk and reward. There is the process of verbatim thinking, which is a more precise form of risk-based analysis, and the fuzzier process that is more gist based. Fuzzy trace theory proposes that during development, adolescents shift from verbatim to gist-based methods.

Future Directions

The examination of risk taking has taken four different perspectives: cognitive, emotional, psychobiological, and social. However, it would be beneficial to the field to integrate the findings and ideas from each of these views. Initial attempts have already been made, such as the Problem Behavior Theory (PBT) and the Biopsychosocial Model. However, whereas PBT depends mostly on sociodevelopmental assumptions and de-emphasizes cognitive and affective development perspectives, the Biopsychosocial Model has difficulty explaining the developmental trajectory of risk taking, and primarily addresses individuals with extreme and chronic behavioral problems. Other than these models, there have been few efforts in cross-perspective efforts. Fortunately, the findings described earlier combining neuroscience with cognitive development theories is a step in the right direction. Findings of this manner should only increase with the development of new technologies, and should shed light on the development of risk taking, as well as preventative measures.

Reducing unhealthy expressions of sensation seeking and risky behavior has been attempted over many years. However, this has proven to be a difficult task as potential interventions such as information, reasoning, and negative advertisements have not been as effective as hoped in dissuading high sensation seekers from pursuing risky behavior. The research concerning dual-process theories and the neuroscientific support suggests there may be very large challenges in attenuating or delaying the shift in reward sensitivity that takes place at puberty psychologically, and instead society should become more vigilant in terms of enforcing laws concerning alcohol and drugs, as well as raising the price of cigarettes and the driving age.

Self-concept, Expressions of the

Anjana Balakrishnan

University of Western Ontario

A Definition and Elaboration

Self-concept describes the mental snapshot that individuals have of themselves (i.e. the sum of their self-perceptions, identities, role relationships, etc.). The organization of the building blocks of self-concept in memory is referred to as *self-concept structure*, whereas the actual information which gets integrated to create self-concept is referred to as *self-concept content*. In order to construct their self-concepts, people are required to appreciate the "I-Me distinction" that the individual "I" actively constructs the "Me" which is considered as an object of social construction. The socially constructed "Me" is highly context-sensitive in that it is shaped by important others, life experiences, and self-reflection. Individuals can have self-concepts that are based in reality, grounded on societal expectations, or built on romanticized notions, and these refer to one's actual self, ought self, and ideal self respectively. Mismatches between actual and ought self-concepts can be a precursor to anxiety, whereas disconnects between the actual and ideal self-concepts can contribute to depression.

Self-concepts vary between individuals given that each person possesses a self-concept with a number of self-aspects (e.g. best friend, daughter, student, etc.) and associated attributes (e.g. respectful). The attributes of each self-aspect may either overlap or be unique. Those who have more self-aspects and less attribute overlap between self-aspects are referred to as having greater *self-concept complexity*. Lower self-concept complexity can be disadvantageous because if one experiences an unpleasant event related to a specific self-aspect (e.g. girlfriend), mental regulation becomes more challenging due to overlap of attributes between self-aspects causing a spillover effect into other self-aspects. This said, higher self-concept complexity is not necessarily better given that in some circumstances this has been linked with poorer well-being due to a difficulty in managing multiple self-aspects. However, self-concept complexity can be meaningful if individuals perceive control over self-aspects because it contributes to a richer view of the self.

Self-Concept Modeling and a Cameo of Academic Self-Concept

A better understanding of how the self-concept is modeled can be gained by tracing back to the early roots of such research. Shavelson, Hubner, and Stanton (1976) have outlined various types of self-concept, and their model of self-concept has exerted tremendous influence on current thought. According to the Shavelson et al. model, self-concept is organized in a hierarchical manner in a pyramidal structure where one's general self-concept is composed of academic and non-academic self-concept. Each type of self-concept is further deconstructed such that academic self-concept focuses in on specific subjects, whereas non-academic self-concept is split into social, emotional, and physical forms. The final layer of the self-concept pyramid has situation specific behavioral manifestations of various components of self-concept. Some other early models of self-concept view general self-concept as interchangeable with global self-esteem or consider self-concept to be similar to self-efficacy in that self-concept involves beliefs about one's level of competence within certain domains which stem from past experiences.

Although there are several types of self-concept, academic self-concept has been extensively studied and much of the current understanding derives from the work of researchers such as Herbert Marsh. Academic self-concept refers to a global perception of oneself within the educational and achievement based domains. Academic self-concept also incorporates two distinct constructs, namely mathematical and verbal self-concept. In an extensive review of academic self-concept, Marsh (1993) has outlined that a model of self-concept which has distinct factors for math, verbal, and non-academic self-concept – the Marsh-Shavelson model – outperforms a general single factor model of self-concept or a model with several second-order academic and non-academic factors. Additionally, the spectrum of subjects subsumed by academic self-concept is not adequately covered by math and verbal factors alone, but rather other factors emerge when assessing subjects such as music. In support of the validity of academic self-concept, evidence shows that domain-specific achievement is linked with specific types of academic self-concept, e.g. strong performance in math links with math self-concept.

Gender Differences and Age Developments in Self-Concept

The self-concept is a dynamic construct which changes both in structure and content depending on what developmental stage one is at. Furthermore, gender plays a vital role in determining what elements get integrated into self-concept at which stage. In the early years of childhood, both boys and girls engage in social comparative processes with the parent who shares their gender (i.e. girls mimic their mothers and boys their fathers). This comparative process results in gender-specific attributes getting integrated into self-concept. Not only do children form their own self-concepts by social comparison, but important others (i.e. parents) actively shape the self-concept of children in ways which are unique for boys as opposed to girls. When girls are told details of their life-stories, mothers use more details when explaining events and there is a greater emphasis on talk about roles

and relationships as well as emotions. In turn, more focus is given to emotions, relationships, how one feels inside, and connectivity when girls as opposed to boys describe their own self-concept. While boys have less detail-rich narratives, their narratives are specialized in that boys zone in on activities where skill-building occurs in their descriptions of self-concept. Young children also have self-concepts where future selves are seen as participating in gender-specific occupations.

While gender exerts influence on self-concept change over time, there are also gender-invariant changes which occur in self-concept during different developmental age periods. As individuals age, their self-concept structures become more complex and integrate more content because individuals come to know more about themselves. The earliest developmental stage (early to late childhood from ages 2 to 10) represents the formative years of self-concept formation. Very young children develop an understanding of themselves as separate entities and differentiate themselves from the social world. At this point, children in the lower end of this age range do not rely on comparison with others to form their self-concept, nor do they consider the viewpoints of others as material for self-concept formation. Additionally, the self-concept of a very young child is biased toward being overly positive and presents the self in a very favorable light. However, children are only able to recall very specific information such as personal preferences or tangible content at this stage, and the recall is in a piecemeal fashion. As children reach the end of childhood and prior to their transition into adolescence, they differ greatly from when they were younger. As opposed to the narcissistic tendencies displayed by younger children, both positivity and negativity are incorporated into the self-view of older children. At this juncture, children compare themselves with others and the opinions of others matter for self-concept formation. The self-concept also is better organized than when children were younger and more information becomes available for integration (e.g. personality attributes, self-other evaluations, and self-esteem relevant content).

Adolescence represents the next developmental stage which spans from when an individual is 11 until 17 years of age. At the lower end of this age range, adolescents shape their self-concept by selectively integrating or excluding the opinions of others depending on which context they are in. Furthermore, the self-concept is structured to allow for lower-order attributes to be grouped into superordinate categories. To illustrate, the superordinate category of ambitious could include attributes such as hardworking and motivated. Older adolescents vary from their younger counterparts in that their self-concepts are richer and more structured. To expand, older adolescents have self-concepts where specific qualities are tied to specific roles (e.g. loyal friend). Older adolescents also give much room in their self-concept to thoughts of their future selves and beliefs about what is personally meaningful. Lastly, individuals at this age start looking to themselves and focus more on trying to become more compatible with their ideal selves as opposed to relying only on others' viewpoints for self-concept formation. Emerging adulthood (i.e. the stage when individuals are between 18 and 25 years of age) represents a developmental stage between childhood and adulthood. Emerging young adults navigate the social world and deal with challenges afforded by multiple occupational paths, romantic relationships, actual and ideal self-concept discrepancies, reconfiguration of their relationships with parents to enable autonomy while preserving social support, etc.

Cultural Differences in Self-Concept

With regard to culture, the lens through which people perceive their world, i.e. self-oriented and achievement driven (i.e. individualistic) vs. other-oriented and harmony driven (i.e. collectivistic), has implications on how the self-concept processes information. Those who are individualistic have a proclivity to view contextual information as self-discrepant, whereas those who are collectivistic are inclined to perceive the social context as self-relevant. In terms of self-relevant emotions, individuals from Western individualistic contexts more often display the self-enhancing emotion of pride, whereas those from Eastern collectivistic contexts more often display the self-effacing emotion of shame. Similarly, the Western self-concept is one where there are strivings to maintain self-esteem, whereas this is not as prevalent in Eastern self-concept. In terms of how the self is represented across cultures, adolescents from Western cultures report multiple self-aspects which display both true self-attributes as well as false attributes which exist outside of one's true self. In contrast, Eastern cultures are tolerant of contradiction and consider that all of an individual's self-aspects are embedded within one's true self and that different self-attributes are not sources of conflict. Another cultural difference is that the developmental stage of emerging adulthood is reached faster in non-Western contexts and clearly demarcated through special rites of passage.

Tapping into Self-Concept: Measurement Methods and Associated Challenges

The self-concept demonstrates malleability over the lifespan and across domains. Not only are there several self-concept measures, but also there are challenges in the accurate assessment of self-concept given the complexity of the self. Self-report measures are commonly used, however the type of information elicited is influenced by the measurement context (e.g. qualities of the experimenter or the research environment, as well as accessibility of self-relevant information). In order to study changes in self-concept over time, both longitudinal and cross-sectional survey techniques are used. A few examples of self-concept measures are the Sears Self-Concept Inventory and the Piers-Harris the Way I Feel about Myself Scale. The Self-Description Questionnaires are a set of scales which look at both academic and non-academic self-concept across childhood to young adulthood. In contrast, the Academic Self-Description Questionnaire focuses solely on academic self-concept. A more hands-on approach to the study of self-concept is through ethnography and studies in the field which allow direct observation of the self in different environmental contexts. Such a research approach could prove beneficial considering that self-concept may not be generalizable across cultures, and ethnographic analysis could allow for a finer level of analysis which takes cultural differences into account. Scientific experiments represent a third means of studying self-concept. Many researchers have begun using implicit association procedures in experiments to study self-concept discreetly. Assessing the validity of self-concept measures has been a key aim of researchers. Both theory-based and methodologically driven approaches can be employed in validational testing. Some of the

approaches employed are as follows: factor analyses, multi-trait multi-method studies, experimental manipulations, employing logic to derive alternative explanations, and using specific data procedures (e.g. causal modeling).

Self-control

Paul F. Tremblay and Lynne Zarbatany

University of Western Ontario

Self-Control Conceptualized

Self-control refers to the voluntary regulation of impulses and temptations that interfere with longer-term goals. At a philosophical level, self-control can be thought of as the price we pay to live in a civilized world. Roy Baumeister, an influential researcher in the field, proposed that self-control is the closest thing we have to the idea of free will. Without some kind of mechanism to resist natural or primal impulses and to imagine and plan our future, we would be unable to co-operate in groups and develop a culture. Freud recognized that we have a mechanism in place, the ego, to control the impulses of the system of primal urges that he referred to as the id. Although Freud developed his own terminology and metaphors, it is clear that he was thinking about self-control.

The problem of self-control and what to do about it was captured best in Homer's great epic poem, the *Odyssey*. Circe, a goddess of magic, describes to Odysseus the obstacles that he will face on his voyage home and how to circumvent them. As they approach the island of the lovely Sirens, Odysseus plugs his men's ears with beeswax and has them bind him to the ship. He alone hears the Sirens' song flowing forth from the island, promising to reveal the future. The song is indeed enchanting, and Odysseus begs to be released from his fetters, but his faithful men only bind him tighter. Themes of self-control also permeate many sacred texts, illustrating failures and victories of self-control in the face of unforgiving temptations. These texts provide useful lessons about prevention and intervention strategies including the benefit of anticipating temptations early and developing a plan of resistance.

Research on Self-Control

Classic Studies on Delay of Gratification

Research on self-control is extensive, overlapping with research on similar constructs such as self-regulation and effortful control. A content analysis of this work reveals two interconnected processes at play. The first process involves application of necessary effort to achieve a delayed or long-term goal, whereas the second process involves inhibition and redirection of attention from competing impulses to achieve the main goal. Reflecting on Walter Mischel's classic research at Stanford University in the late 1960s on self-control in children, we can imagine a 4-year-old child struggling to resist the temptation to take one marshmallow now in order to receive two marshmallows in the near future (i.e. 15 minutes). In those studies, some children gave in to temptation right away, others struggled for a while but also gave in, and about 30% of children persisted and waited for the two marshmallows. Mischel and his colleagues showed that effective use of distraction and imagery strategies enabled children to obtain more marshmallows by delaying gratification. Children used various techniques to distract themselves, including imagining the marshmallows as something (e.g. white clouds) other than candy. Indeed, one way to promote and protect distal goals over proximal impulses and temptations is through cognitive reconstrual of temptations in an abstract way. When reconstruals fail, and the temptation is undefeatable, or when self-control fails completely such as in addictions, external help is often required. Mischel's research also provided evidence that early individual differences in delay of gratification predicted better friendships, fewer behavioral problems, and higher Scholastic Aptitude Test scores in adolescence, and academic and occupational achievement in adulthood. Whereas Mischel and colleagues used real choice delay tasks (e.g. one marshmallow now or two later), another common approach is the hypothetical choice delay task (e.g. 10 dollars now, or 50 dollars in one year), which has been used with adults in various research domains such as behavioral economics.

Diary Studies of Self-Control in Daily Life

Like self-awareness, the processes of self-control are activated upon waking up. The first act of self-control may be the decision to get up or remain lying in bed. Everyone is tempted by desires on a daily basis: a bit of extra sleep in the morning, another cup of coffee, taking a day off work, texting on the way to work, sexual impulses, power, and social dominance. Baumeister and colleagues asked a group of adults to keep track of their daily desires and temptations and how successful they were at inhibiting the urges. The participants reported having desires, such as more sleep, sex, and playing games for about half of their waking hours and fighting off temptation to 38% of those desires (Hofmann, Vohs, & Baumeister, 2012). Most people would admit that they fail at self-control in some aspect of their life, and some face devastating consequences. Clearly, self-control can be difficult, and people may fail to behave as they intend.

The Ego Depletion Hypothesis

Roy Baumeister and his colleagues proposed that self-control is akin to a limited resource in an energy model. Like a muscle that is fatigued and fails after much exertion, self-control eventually fails at resisting impulses. The proposition was referred to as the ego depletion

hypothesis (Baumeister, Vohs, & Tice, 2007). In several studies, Baumeister and colleagues investigated participants' self-control after they had previously inhibited a response such as not eating chocolate cake that was placed in front of them and instead consuming unappetizing radishes. The effect of resisting the chocolate cake was to impair performance on unrelated tasks that required perseverance in the face of failure. Other processes, such as making choices, were also found to cost energy and have a debilitating effect on later self-control. Although Baumeister and colleagues first explained ego depletion as the result of glucose depletion in the brain, they later abandoned this notion in favor of a resource allocation explanation. Like a muscle, they argued, the brain is never completely depleted, but rather conserves and reallocates energy where needed. Taken together, two meta-analytic studies performed on hundreds of lab studies suggest that the robustness of the depletion effect varies depending on the measures used to assess self-control. Replication of the few daily diary studies of people's real experiences in self-control will no doubt help refine the ego depletion model.

Executive Functions and Effortful Control

Another area of research focuses primarily on neuropsychological processes underlying self-control. Cognitive tasks have been developed to assess executive functions, or processes that involve neural networks in the prefrontal cortex of the brain, including attention focusing, attention shifting, working memory, and inhibitory and activational control. Executive functions allocate and inhibit resources to various cognitive processes including self-regulation and therefore prevent us, under normal circumstances, from being derailed by the motivational system of self-gratification. The neurotransmitter dopamine is involved in the mesolimbic network of the brain responsible for motivation. Effortful control, a related construct (e.g. Rothbart, Sheese, & Posner, 2007), involves persistence, inhibitory control, focused attention, and delay of gratification, and is assessed in early childhood using laboratory tasks and observer reports. Effortful control processes have been linked to the neurocognitive network of executive attention that draws upon a number of different regions of the brain including the prefrontal cortex and the anterior cingulate cortex (Rothbart et al., 2007). Effortful control predicts a number of behavioral outcomes such as prosocial, lower antisocial behavior, and empathy.

Trait Self-Control

Several self-report measures have been developed to measure dispositional or trait self-control. These are quite heterogeneous in content, with some assessing self-control directly (e.g. Self-Control Scale; Tangney, Baumeister, & Boone, 2004) and other measures assessing related concepts such as impulsivity or sensation seeking. The Self-Control Scale includes items such as "People would say that I have iron self-discipline," and "I refuse things that are bad for me." A number of studies by Baumeister and his colleagues have suggested that people with high self-control are not necessarily better at resisting temptation, but they are better at avoiding it. Avoidance of temptations by minimizing exposure to situations that invite failure is particularly important given that such a strategy would not deplete the limited cognitive resources as much as would brute resistance. Future scale development could focus on the specific avoidance strategies used in particular domains such as dieting and addictive products.

Developmental Differences

Self-control steadily improves from infancy to adulthood. Newborn infants have no control over their emotions, but as they gain muscular control, they begin to regulate arousal by shifting eye gaze or turning their heads away from distressing stimuli. Sensitive caregivers are partners in emotion regulation, soothing distressed infants, removing them from upsetting contexts, and serving as a secure base for infant exploration once mobility is achieved. In childhood, the development of self-control accelerates, and children learn to exchange impulsive behavior for self-regulated techniques such as delay of gratification. Initially, parents scaffold their children's self-control by teaching rules for appropriate conduct, enforcing rules through rewards and sanctions, and modeling self-control strategies. Eventually, children internalize the rules and regulate their own behavior. Participation in early childcare and school settings reinforces and refines the socialization process.

Self-control problems in adolescence are of particular interest because mortality rates increase dramatically due to accidental fatalities. This seems counterintuitive given earlier developments in self control, but sensation and reward-seeking are especially high during adolescence, and the prefrontal cortex is not sufficiently well developed to inhibit risky decision-making (Casey, 2015). The social context plays a strong role; adolescents are particularly susceptible to peer influence, and will engage in dangerous behavior to gain peer approval. Two opposing forces have been described within a variety of dual reward-driven vs. harm avoidant models, and behavioral research investigating the influence of immediate reward feedback on gambling tasks shows the highest risk behavior among adolescents. Sensitivity to motivational cues appears to be enhanced during adolescence, supported by changes in areas of the brain associated with dopamine, including the striatum. It is likely that this particular pattern of high novelty-seeking and risk-taking among adolescents was adaptive in evolutionary history as adolescence marked the critical beginning of the reproductive period.

Future Directions

Many societies and cultures will no doubt continue to place a heavy emphasis on consumerism and instant gratification, with advertising often in a tug of war with self-control over the need for various products. In the end, evidence-based recommendations will probably point to the salutary effects of simpler, slower-paced, mindful lives. Researchers will continue to test the ego depletion hypothesis and specify processes involved in allocation of self-control in daily life. The few daily diary studies investigating people's impulses and the methods they use to self-regulate provide another useful methodological approach for future research. At the same time, applied researchers will continue to test self-regulation strategies in childhood and develop interventions such as mindfulness training to improve children's self-control at school. Preliminary findings indicate that these efforts offer promise for enhancing children's social and academic success.

Self-construal

Susan E. Cross

Iowa State University

The term *self-construal* was first coined by Markus and Kitayama (1991), who used it to describe Western versus East Asian conceptions of the self. Although research on the role of the self in cognition, emotion, and motivation was several decades old by this time, most of that research had been conducted in Western cultural contexts, and researchers tended to assume that the nature of self-views and their role in psychological phenomena were universal. In Western European and European American cultural contexts, the self is assumed to be independent of others, defined largely by internal traits, personal preferences, wishes, abilities and goals that are presumed to be fairly consistent across situations. The pursuit of personal uniqueness and the supremacy of individual goals over group goals characterize this conception of the self. Markus and Kitayama labeled this the *independent self-construal*. They contrasted this conception of the self with the prototypical self-construal of Japanese people, the *interdependent self-construal*. In this conception, self-definition is based on one's place in relationships, one's roles (mother, son, student, neighbor), and one's group memberships; relational or group goals are often more important than one's personal goals. The self is assumed to be malleable and adaptable; individuals seek to fit into their roles and relationships rather than to demonstrate a consistent self across situations.

After Markus and Kitayama's initial characterization of independent/interdependent self-construals, researchers made further distinctions in types of interdependent self-construal. Drawing upon research on gender differences in Western contexts, Cross and Madsen (1997; see also Cross, Bacon, & Morris, 2000) argued that Western women were more likely than men to think of themselves in terms of close relationships, leading to a *relational-interdependent self-construal*. Others have distinguished relational-interdependent self-construals from collective-interdependent self-construals, in which group members are highly self-defining.

Researchers today conceive of these dimensions of self-construals as accessible to members of virtually all cultural contexts, but cultures often emphasize one dimension more than the other (i.e. East Asian contexts emphasize interdependence, and European

American contexts emphasize independence). As a result, self-construal theory has opened up a multi-dimensional view of selves that has enhanced research within cultures as well as across cultures.

Cognition

People with highly interdependent self-construal tend to be more sensitive to the context, whereas people with highly independent self-construal tend to be relatively insensitive to the context. This was first demonstrated in work that showed that East Asians were less likely than European Americans to make situational attributions for others' behavior. Likewise, Japanese women's spontaneous self-descriptions are more sensitive to the specific context than were the self-descriptions of American women. Priming independent or interdependent self-construal also leads to differences in context-sensitive or context-free cognitive processes (such as the Embedded Figures task, where one must find a small geometric figure within a larger figure). Self-construal is linked to the tendency to see connections among objects or people (related to interdependent self-construal) or make distinctions between objects or people (related to independent self-construal; see Cross, Hardin, & Gercek-Swing, 2011, for a review).

Emotion

Interdependent self-construal is related to socially engaging emotions such as guilt or feelings of relatedness, whereas independent self-construal is related to socially disengaging emotions such as anger or pride (Kitayama, Mesquita, & Karasawa, 2006). Their research showed that there is a stronger relation between positive socially engaging emotions and general positive emotions for Japanese than for Americans, whereas positively disengaging emotions were more strongly related to general positive emotions for Americans than for Japanese. Other research reveals that East Asians tend to value low arousal emotions (such as calm, peaceful) more than do Westerners; Westerners value high arousal positive emotions (such as enthusiastic or excited) more than do East Asians (Tsai, 2007). Suppression of emotion, especially negative emotion, is typically linked to poor health and well-being for Westerners, but this association is weaker for East Asians, presumably because interdependence is associated with the approval of frequent suppression of emotions that may disrupt the harmony of relationship or group.

Motivation

Independent self-construal has been linked to the desire to be unique and different from others and to pursue personal goals, whereas relational and interdependent self-construal have been linked to the desire to maintain harmonious relations with others and important ingroups and to pursue group goals. Markus and Kitayama (2004) described these as disjoint (independent) vs. conjoint (interdependent) forms of agency. Consistent with this

view, relational reasons for goal pursuit (e.g. doing it for a close other) were strongly related to goal striving for people with highly relational self-construals in both the US and Japan.

A vigorous debate erupted after the publication of a review of East–West differences in self-enhancement by Heine, Lehman, Markus, and Kitayama (1999). These authors contend that the existing literature on the positive consequences of self-enhancement are due to research in Western societies, where the independent self-construal is constructed and maintained by attention to and enhancement of one's internal attributes, abilities, and goals. They argued that in societies as Japan and China, a critical consequence of interdependence is that individuals acknowledge their faults and flaws and strive for self-improvement, so as to maintain harmony in relationships. Heine et al.'s (1999) review found East Asians reported lower levels of self-esteem than did Westerners, and subsequent meta-analytic reviews of the literature supported this claim. Others, however, argued that self-enhancement is a universal motive, and that researchers had overlooked the important domains of self-enhancement for people with highly interdependent self-construals (Sedikides, Gaertner, & Vevea, 2005).

Likewise, variation in self-construal relates to the motivation to be consistent, as demonstrated in studies of cognitive dissonance. For many years, researchers failed to replicate cognitive dissonance results in East Asian societies (especially Japan); they presumed the consistency motive was not as central in the interdependent Japanese cultural context as in the West. Later, others demonstrated that Japanese participants experience less dissonance than Western participants when faced with inconsistency in personal choice, but they experience similar levels of dissonance when faced with inconsistency in choices for others. This indicates that maintaining consistent or appropriate behavior in specific relationships or roles is a powerful motivator for people from East Asian contexts with highly interdependent self-construals (Hoshina-Browne et al. 2005).

Finally, self-construal is associated with differences in self-regulation and means of exerting control. The focus on appropriate behavior in roles and relationships that characterizes the interdependent self-construal contributes to a prevention-focused regulatory style, in which the individual is primarily oriented toward avoiding undesired end-states. In contrast, the focus on expression of personal aspirations and goals and the emphasis on self-fulfillment characteristic of the independent self-construal contribute to a promotion-focused regulatory style, in which the individual seeks to approach desired end-states. Similarly, in stressful situations, East Asian individuals are more likely than Westerners to prefer secondary control (adjusting the self to fit the situation); Westerners, in contrast, prefer to exert primary control (attempting to change the situation).

Interpersonal Behavior

People with highly relational self-construal are more likely to engage in self-disclosure, perspective taking, and interpersonal responsiveness in a new roommate relationship than are lows on this dimension (see Cross et al., 2011 for a review). When interacting with strangers, high levels of interdependent self-construal are associated with a variety of other-oriented behaviors, such as sitting closer, higher levels of mimicry, and lower levels of selfishness, compared to lows. Cross-cultural research has found that self-construal is

related to a variety of communication processes; interdependent self-construal is associated with indirect forms of communication and non-confrontational approaches to conflict, whereas independent self-construal is associated with direct communication and confrontational or dominating strategies in conflict situations.

Methodological Issues

Researchers often use cultural background as a proxy for self-construal; members of East Asian cultures are assumed to have more well-elaborated interdependent self-construals, whereas members of Western European and European American cultures are assumed to have more well-elaborated independent self-construals. Other mechanisms may be responsible for some cultural differences that have been attributed to self-construal. Several measures of self-construal have been developed to test the role of self-construal more specifically (see Cross et al., 2011 for a review). A new seven-dimensional measure of self-construal has been examined across a very large sample of countries (Vignoles et al., 2016).

An early meta-analysis of studies using the common independent/interdependent self-construal measures found that the expected cultural differences in self-construal are not always found (Oyserman, Coon, & Kemmelmeier, 2002). This led to further research on the ways that reference groups may influence responses on Likert-scaled items, obscuring group differences in self-construal. Kitayama and his colleagues (Kitayama, Park, Sevincer, Karasawa, & Uskul, 2009) also argued that cultural mandates to be independent or interdependent are reflected in a wide range of cultural tasks (e.g. to stand out or to fit in, to pursue group goals or pursue individual goals). These cultural tasks are often achieved via a variety of psychological tendencies (e.g. self-criticism vs. self-enhancement, socially engaging vs. disengaging emotions) that may not require conscious deliberation and may vary across situations. Consequently, explicit measures of self-construal may not capture the implicit or automatic ways that people respond to cultural mandates to be independent or interdependent. These arguments highlight the need for a wider variety of implicit or indirect measures of self-construal, and for conceptual approaches that take account of the critical role of implicit processes, social norms and roles, and other inter-individual processes that shape behavior.

Future Directions

There is a growing body of research on the social neuroscience of self-construal, which has examined the neural mechanisms that mediate cultural differences in self-related cognitive processes. Many of these studies have primed independent or interdependent self-construal and have observed differences in the associated neural correlates. Other studies have combined self-construal priming with the use of populations from East Asian and Western contexts to examine how independent or interdependent self-construal may have different neural correlates in the two cultural contexts (see Han, 2013, for a review). This burgeoning field of cultural neuroscience may help uncover new ways that self-construal influences behavior and has the potential to help explain the ways that self-construal is shaped by developmental or socialization processes.

One of the critical issues facing self-construal researchers is the need to study groups outside the common East Asian and Western European/European American populations. Although many societies in Africa, Latin America, Eastern European, and Pacific Island contexts may be relatively collectivistic, it is unknown the extent to which interdependent or relational self-construals capture their conceptions of self. Such work may result in the identification of new dimensions of self-construal that will enhance our understanding of the cultural construction of the person.

There are many more contexts, processes, and psychological phenomena that may be linked to variation in self-construal. Researchers have only recently begun to examine the influence of self-construal in the development and maintenance of romantic relationships, and further research in this area may help explain cultural differences in relationship processes and outcomes. Likewise, some researchers have begun to investigate the role of self-construal in organizational behavior, consumer behavior, and other work or business settings, but considerable terrain in these areas remains unexplored.

Self-efficacy

Maria Gerbino

Sapienza University of Rome

Self-efficacy beliefs (SEBs) are an individual's beliefs about his or her own capacity to reach certain objectives through the orchestration of his or her own course of action. SEBs were conceptualized by Albert Bandura (1977, 1997) and reflect individuals' ability to exercise control of their own lives. SEBs are at the core of an agentic perspective of human functioning that emphasizes individuals' capacity to influence their own functioning and the events of their lives (Bandura, 1986; 1997).

Overall, in the last 30 years, findings from experimental, clinical, longitudinal, and correlational studies have attested that a variety of self-efficacy beliefs contribute to better performance and effective functioning across contexts and ages. Most research has paid attention to specific self-efficacy beliefs concerning the diverse domains of functioning (e.g. education, interpersonal relations, and health). Successful functioning in different areas may in fact require different capabilities, and individuals' appraisals of those capabilities may substantially differ across domains.

In the following sections, we will first address the main intra-individual processes associated with SEBs. We will then present the main correlates to SEBs in the areas of functioning that are especially important for individuals' personal and social adjustment (i.e. interpersonal and emotional functioning, educational achievement, health functioning and organizational functioning).

Intra-Individual Processes Activated by SEBs

SEBs influence a variety of cognitive, decisional, motivational, and affective processes that, in turn, sustain effective performance and enable people to exercise some control over the events of their lives (Bandura, 1997).

With regard to cognitive processes, SEBs influence how individuals anticipate the tasks and problems they have to face. Highly self-efficacious people tend to maintain a broader view of the problem. They anticipate successful scenarios and are more focused on problem-solving

strategies. In the face of strong demands, setbacks or failures especially, highly self-efficacious people tend to maintain good analytical thinking and remain task-oriented.

SEBs are also important cognitive guides that orient the decisions and, in particular, the selection of goals that individuals set for themselves. People usually only undertake those tasks and situations that they feel capable of handling. They avoid setting goals for themselves that they consider unreachable and do not engage in tasks that they perceive as being beyond their capacities. Therefore, SEBs lead people to put long-term effort into developing specific capabilities and career paths (see Career Self-efficacy on p. 1445 of this volume).

When it comes to motivational processes, highly self-efficacious individuals are more likely to attribute their failures to factors that may be modified and controlled, such as lack of effort. This attributional style contributes to counteracting despondency while persisting in goal-oriented behavior. Furthermore, more self-efficacious individuals set for themselves difficult but reachable goals and feel more committed to them. When facing difficulties, they intensify their efforts and seek out effective problem-solving strategies. SEBs also sustain people's ability to overcome obstacles or impediments, to regulate behavior over time and to perceive obstacles as challenging.

Finally, SEBs affect the negative emotional states that individuals experience when they face difficulties. In fact, SEBs reduce self-debilitating thoughts and counteract negative emotional reactions to facing difficulties. Individuals who believe they are not capable of controlling stressors are more prone to dwell on their low coping capacities and perceive the environment as more dangerous, and this contributes to improving their distress and anxiety. Similarly, people who believe they are ineffective in controlling their own dysfunctional thoughts when faced with difficulties are not only more distressed and anxious, but they also experience more depressive feelings.

Self-Efficacy and Interpersonal Functioning

Research has underlined that SEBs in interpersonal relations (in particular, relationships with friends and within family) promote adaptive interpersonal functioning that, in turn, may sustain psychosocial adjustment. During adolescence, when deviant peers may jeopardize adolescents' self-regulation capabilities, SEBs in resisting transgressive peer pressures counteract adolescents' involvement in delinquent and risky behavior (Bandura, 2006). In both youths and adults, higher SEBs in one's capability to establish and maintain positive relations with others (i.e. social self-efficacy) have been found associated with fewer depressive feelings. More socially efficacious individuals can in fact create more supportive and enduring interpersonal relations that probably help them to face discouraging situations (Bandura, 1997).

More recently, research has addressed SEBs concerning the ability to assume others' perspective, namely, empathic SEBs. Empathic SEBs have an important role in sustaining prosocial behaviors (i.e. behaviors that benefit others) over time, which promotes adjustment and life satisfaction at different ages (Alessandri, Caprara, Eisenberg, & Steca, 2009).

Furthermore, family relations are of particular relevance to interpersonal functioning. In particular, research has addressed parental SEBs, which are the beliefs that parents hold about their capacity to care and promote their children's development (Bandura, 2006).

Efficacious mothers experience higher well-being, lower depression, closer attachment to their children, and better relationships with their partners. As children grow up, efficacious parents more effectively monitor children, more openly communicate with their children, give them more support and are more capable of setting effective limits (Bandura, 2006). With regard to children's role, filial SEBs (i.e. children's perceived ability to establish and maintain positive relations with their parents) in adolescence contribute to more open communication and less escalation in conflict with parents over time. Both familial SEBs contribute to higher levels of family satisfaction (Caprara, Scabini, & Regalia, 2006).

Self-Efficacy and Emotion Regulation

Social-cognitive theory has strongly emphasized the role of SEBs in controlling the negative effects of subverter emotions, such as anxiety and depressive feelings. In the last 10 years, researchers have proposed the construct of Regulatory Emotional Self-Efficacy beliefs (RESEs) and examined their role in individual adjustment. Specifically, RESEs concern people's perceived capacities not only to modulate the overwhelming experience of different negative emotions (e.g. fear, despondency, anger, guilt and shame), but also to experience and express positive emotions (e.g. joy, satisfaction, and happiness). Those two distinct RESEs are respectively associated with lower negative effects and higher positive affects (Alessandri, Vecchione, & Caprara, 2014). In particular, longitudinal studies have found that RESEs contribute to maintaining higher levels of self-esteem and experiencing fewer depressive feelings over time. Yet, SEBs about regulating negative emotions are important for counteracting adolescents' shyness and sustaining higher life satisfaction. RESEs also contribute to perceived self-efficacy in interpersonal relations. In particular, individuals who feel capable of expressing positive emotions have higher perceived capacities to take on others' perspectives, whereas those who feel capable of modulating negative emotions feel more capable of handling interpersonal relations, particularly relations with parents in adolescence.

Self-Efficacy and Educational Attainment

Different studies have shown that SEBs are associated with students earning better grades across all school levels (i.e. elementary, middle and secondary school, and university), even when controlling for past performance. In particular, students' and teachers' SEBs have been more frequently examined in promoting academic achievement (Pajares, 2007).

Among students, the most relevant dimension of SEBs is related to self-regulated learning and concerns students' perceived ability to influence their own learning process through self-regulation. Self-regulated students set proximal goals, monitor their own behavior, anticipate how to cope with the obstacles they may encounter, evaluate their progress toward their goals and modify their behavior to accomplish them. Students who feel more capable of regulating their learning activities are more capable of planning their study, self-motivating (e.g. finding a place to study that facilitates concentration), more persistently facing difficulties and also effectively solving academic problems. They have higher aspirations and more accurately evaluate their performance.

Teachers also play a key role in improving students' performance in school. More efficacious teachers are better at managing their classrooms, promoting learning, giving more emotional support, being less critical and motivating difficult students.

Self-Efficacy and Health Functioning

SEBs play an important role in the adoption and maintenance of health-promoting behaviors – such as regular physical exercise, healthy diet, and smoking and alcohol reduction, and the management of chronic diseases, such as diabetes, arthritis, and cancer (Bandura, 2005).

As for academic achievement, it has been found that self-regulatory SEBs are crucial for successful behavioral change. Research has found that, for example, SEBs for overcoming barriers to physical exercise are important predictors of the practice and maintenance of physical activities. In the longer term, people's beliefs in their capabilities to restore control on behavior after a failure or breakdown (e.g. a relapse in alcohol use) are important. Individuals who feel inefficacious in coping with obstacles or recovering after a failure tend to be more discouraged, interpret failure as a sign of a lack of capabilities, and are more likely to give up their goals.

Regarding the management of chronic disease, research findings have shown that better health outcomes in chronic illness are associated with higher SEBs about adopting those self-care behaviors that contribute to controlling the symptoms of illness (Marks & Allegrante, 2005). For example, SEBs in the self-management of diabetes are associated with better adherence to treatment, and thus to more frequent testing of blood glucose, more regular use of medication and lower levels of glucose in the blood. Furthermore, SEBs about tolerating pain are associated with less physical disability, less pain, fewer depressive symptoms, and less use of opioid medication, especially in disease such as cancer or arthritis.

Self-Efficacy and Organizational Functioning

SEBs have been associated with performance and a variety of indicators of well-being and effective functioning in organizational contexts. In particular, most research has addressed work-related SEBs that concern employees' perceived abilities to manage the specific activities that they are required to perform in their organizations. Work SEBs contribute to individuals' capacities to cope with work demands and identify opportunities in different work contexts. Efficacious workers are more able to bear work overload and use effective coping strategies (Bandura, 1997). They achieve better job performance, especially when the roles in the organization are clear. Work SEBs also contribute to sustaining job satisfaction, especially in unstable conditions such as organizational change. SEBs also reduce the negative effects of work conflict, and protect against the risk of burn-out, especially in stressful professions such as teaching and nursing.

More recent studies have shown that people who feel efficacious in their work tend to feel more engaged with it, have a more positive view of the key roles of their organization (e.g. colleagues, supervisors, and top management) and are as a result satisfied with and engaged in their jobs (Consiglio, Borgogni, Di Tecco, & Schaufeli, 2016).

Career Self-efficacy

Conceptualization

Self-efficacy has been an influential construct in psychology since first originated by Albert Bandura in the 1970s as a component of social learning theory and later in the development of social-cognitive theory. Career self-efficacy occupies a central role in social-cognitive career theory, which has been an influential framework for explaining how individuals make career and educational decisions and achieve varying levels of career success and satisfaction in the workplace.

As a basic principle, Bandura describes self-efficacy as pertaining to people's judgments about their capabilities for success in completing different types of actions. Self-efficacy thus describes an individual's confidence about performing a particular behavior, expectations for success in that behavior, or beliefs about one's capacity for agency or self-direction. Self-efficacy expectations have been shown to influence whether an individual will attempt a certain behavior, how much effort will be put into the behavior, and how long the specified behavior will be sustained. Thus, a stronger sense of self-efficacy is associated with a positive attitude about having the available (internal and external) resources to master difficult tasks. Self-efficacy does not necessarily reflect an objective reality or the actual available resources and skills one may have, but the belief of what one can accomplish.

Social-Cognitive Career Theory

Since the 1980s, Robert Lent, Steven Brown, Gail Hackett, and Nancy Betz have been influential in vocational psychology in the development of social-cognitive career theory (SCCT) and in propelling the large body of research and interventions that have stemmed from that framework. SSCT emerged as an extension of Krumboltz's social learning model of career decision-making and was conceptualized as a broad and integrated model for understanding

the development of academic and career interests, the implementation of career choices, and career performance. In recent work, Lent and colleagues have also applied the SCCT model to understand work and life satisfaction.

SCCT highlights the dynamic interplay between three main social-cognitive variables, self-efficacy beliefs, outcome expectations, and personal goals, in shaping career behaviors. Career self-efficacy focuses on those self-efficacy beliefs that relate to career-related domains of behavior, such as career skills or decision-making. In general, people are more likely to prefer activities and choose occupations that they believe are aligned with their perceived self-efficacy.

In addition to the three sets of social-cognitive variables, SSCT specifies a variety of personal, contextual, and experiential factors that interact reciprocally to impact career interests, choices, and performance. While SCCT views the individual as an active agent in career processes, past and current environmental conditions are also recognized as influential. For example, high levels of contextual supports and low perceived barriers may enhance a person's level of perceived self-efficacy. An individual's learning opportunities while growing up may also impact the development of academic and career skills and their self-efficacy beliefs in those domains. Additional individual factors such as personality dispositions, gender socialization experiences, and ethnic identity also influence career development processes, including career self-efficacy. For example, a person who is prone to experience negative affect (e.g. anxiety) may be more sensitive to environmental challenges, and as a result may perceive more obstacles and fewer supports and report lower self-efficacy than a person who experiences more positive affect. Gender role socialization may influence a person's perceived self-efficacy along gender stereotypical lines and thereby circumscribe the development of career interests and goals.

A substantial body of research has accrued to support the tenets of the SCCT model, especially with regard to the importance of career self-efficacy. In contrast with aspects of personality that are considered generally stable and generalizable across contexts, self-efficacy is viewed as dynamic and shaped through the ongoing and bidirectional interplay of individual and environmental factors. Although career self-efficacy may be shaped by genetics and early childhood experiences, social-cognitive theory purports that self-efficacy beliefs are malleable and subject to revision based on changes within the person, in their behavior, or in some aspect of the environment. Interest in the construct of self-efficacy among researchers and practitioners relates to possibilities for enhancing self-efficacy through targeted intervention focused on individual beliefs or behaviors or on environmental conditions. Self-efficacy is also domain specific, such that a person may have high self-efficacy in one domain, such as athletics, but low self-efficacy in another domain, such as social skills. With regard to the proposition that self-efficacy shapes career interests and choices, research has documented the relationship between perceived self-efficacy in specific skill domains and the choice of occupations aligned with those skills. Gender differences in the choice of occupations (e.g. women are more highly represented in "social" occupations and men are more highly represented in "realistic" occupations) reflect traditional gender differences in perceived self-efficacy in the social and realistic (technical and hands on) domains. Meta-analyses analyzing a large number of studies confirm the contribution of self-efficacy in explaining career interests, career choice, performance in school and work, and performance goals.

Career Decision Self-efficacy

Career decision self-efficacy is a derivative of SCCT and represents a specific domain of self-efficacy that has received significant research attention. Choosing a career path is complex because of multiple potential career pathways and the numerous relevant personal considerations that complicate decision-making in a constantly evolving world of work. In the changing global marketplace, people have to frequently re-evaluate their career choices, and modify their behaviors and goals accordingly. For vocational psychologists, addressing career decision self-efficacy is integral for helping individuals to make satisfying career choices. Career decision-making self-efficacy is a person's beliefs about his or her capability to perform tasks necessary for making career decisions, including (1) accurate self-appraisal, (b) gathering occupational information, (3) goal selection, (4) planning for the future and (5) problem solving. These competencies are captured in the career decision self-efficacy scale, published in 1983 by Taylor and Betz. Existing research has found that higher levels of career decision-making self-efficacy contribute positively to adaptive career beliefs and persistence in academic studies, and inversely with career indecision and fear of career commitment. Positive relationships have also been documented between career decision-making self-efficacy and self-esteem.

While career decision self-efficacy is distinct from more stable aspects of personality, research reveals relationships between career decision self-efficacy and a number of the Big Five personality factors. For example, while openness to experience, conscientiousness and extraversion have been positively associated with career decision self-efficacy, neuroticism has been negatively associated with decision-making self-efficacy. Career decision-making self-efficacy has also been negatively associated with trait anxiety and negative affect and positively associated with positive affect. These findings support the notion that individual personality dispositions influence career self-efficacy beliefs, with positive dispositions supporting self-efficacy and with negative thinking during the decision-making process relating to lower self-efficacy. A similar pattern of correlations has been found across European American samples, African American college students, and Latino middle-school students. Research has also examined the relationship of career self-efficacy with more malleable dimensions of personality and ability. Research by Di Fabio and colleagues in the Italian context has found that emotional intelligence, as assessed both as a trait and performance-assessed skill, explains career decision-making self-efficacy beyond the effects of fluid intelligence and the Big Five personality factors.

In consideration of the role of environmental factors in the SSCT model, environmental supports have been identified as a mechanism for enhancing career self-efficacy. Support for career decision-making from parents and teachers can be particularly important for adolescents who are in a developmental phase of self-exploration – often characterized by anxiety and indecision. Lent and Betz found that career self-efficacy mediated the relationship between social support and career optimism. The findings suggest that social support can foster career optimism by increasing one's confidence in being able to make career decisions. When parents can support children's activities that enhance work-related skills (i.e. provide opportunities for mastery), share their own career-related strategies and skills (i.e. provide modeling), and offer positive reinforcement by verbally encouraging their offspring (i.e. social persuasion), adolescents gain confidence in career-related decisions.

Intervention

According to social-cognitive theory as devised by Bandura, self-efficacy can be fostered by focusing on (1) performance accomplishments, (2) vicarious learning, (3) social persuasion, and (4) physiological affective states. These four sources of efficacy information can be used to inform career counseling and psychoeducational interventions. Interventions to enhance self-efficacy might seek to strengthen an individual's beliefs about his or her capabilities through incrementally graded success situations that allow the individual to succeed rather than fail prematurely. Self-efficacy expectations are based upon prior performance accomplishments or mastery experiences, such that successful performance on a particular task fosters an individual's determination to master future demands. Vicarious learning experiences, such as observing a model similar to oneself in age, gender, or race engaging successfully in work situations, can also foster self-efficacy and confidence to engage in activities that otherwise may not be attempted. Social support and persuasion may also be employed to encourage individuals to attempt new and challenging tasks and to persist despite fears of failure. If physiological affective states are undermining a person's sense of efficacy, relaxation exercises or other types of cognitive restructuring exercises might be helpful.

Many psychoeducational interventions have been developed that incorporate these principles. Sullivan and Mahalik, for example, designed a structured career counseling group to increase career-related self-efficacy by focusing on the four specified sources of efficacy. Results indicated that women who participated in the group that incorporated performance accomplishments, vicarious experiences, emotional arousal, and verbal persuasion increased in their career decision-making self-efficacy as well as vocational exploration and commitment. Similar workshops developed by Gati and colleagues with Israeli soldiers transitioning to the work force were also shown to enhance career decision self-efficacy among participants. McWhirter, Rasheed, and Carothers developed and implemented a nine-week career education module for high school sophomores that provided active learning experiences 50 minutes per day pertaining to career decision-making, job hunting, and workplace expectations. In comparison with students enrolled in a health education class, the students enrolled in the career education class demonstrated increased decision-making self-efficacy and vocational skills self-efficacy at post-test and at a nine-week follow-up.

Future Directions

Research provides wide support for the importance of career self-efficacy for career interests, choice, performance, and satisfaction. Substantive research also documents the relationship of career self-efficacy with the range of personal, social-cognitive, and environmental factors that make up the SSCT model. The body of research on career self-efficacy has expanded over time to include its interaction with a broad range of personal and contextual variables and its contribution to a variety of career and life outcomes. Although SSCT and self-efficacy have been studied across diverse racial, ethnic, and national contexts, self-efficacy has been critiqued as a construct that places too much responsibility on the individual and not enough on societal factors. More research is needed on how self-efficacy and other social-cognitive variables interact with culture, race, socioeconomic status, ableness, and sexual orientation and with career supports and barriers to

influence career choice and success. The impact of racism and other forms of discrimination on perceived self-efficacy deserves further attention. Although self-efficacy is a promising construct for intervention related to its modifiability, more research is needed to fully document the processes that enhance self-efficacy. In addition, research should explore whether those enhancements are sustained over time and translate into more satisfying career choices that overcome socio-economic barriers and systematic oppression. More intervention research on self-efficacy interventions needs to be completed with varied populations with attention to how the interventions should be tailored in deep and meaningful ways to enhance their effectiveness for specific populations.

Self-esteem, Expressions of

Dario Cvencek and Anthony G. Greenwald

University of Washington

Self-Esteem

Self-esteem remains one of social psychology's central constructs, despite disagreements about its theoretical interpretation and methods of measurement. This entry provides an overview of alternative views of structure and empirical controversies about the function of self-esteem in personality. Special emphasis is placed on recent advancement in implicit measurement of self-esteem, with a brief discussion of implications for developmental research.

Many personality theorists have characterized self-esteem as an essential ingredient of personality. Remarkably, however, there are wide variations in their conceptions of how to conceive the functioning of self-esteem. For Carl Rogers, self-esteem was essential both to psychological health and to the likelihood of achieving life goals. Similarly, for Abraham Maslow, self-esteem was a basic human need, fulfillment of which contributed to self-actualization. Gordon Allport conceived self-esteem as one of the seven aspects of the self that characterize the healthy, mature, adult personality, also viewing self-esteem's development as occurring in early childhood. Rogers, Maslow, and Allport all associated high self-esteem with a broad range of desirable outcomes, a view similar to that of psychoanalytic theorists who conceived low self-esteem as maladaptive (e.g. Alfred Adler's "inferiority complex" and Karen Horney's "self-contempt").

Structure of Self-Esteem

Self-esteem is widely conceived as a relatively stable trait, consisting of positive self-regard or attitude, and arising from normal maturation. At the same time, there exist multiple conceptions of self-esteem's structure, ranging from relatively simple networks to multi-faceted evaluative schemas. At the simpler end are ideas of self-esteem as "a positive or

negative attitude toward a particular object, namely, the self" (Rosenberg, 1965, p. 30) and "the association of the concept of self with a valence attribute" (Greenwald et al., 2002, p. 3). At intermediate levels of complexity are cognitively based views of self-esteem such as "a personal judgment of worthiness that is expressed in the attitudes the individual holds toward himself" (Coopersmith, 1967, p. 5) and more affectively based ones such as "feelings of affection for oneself, no different, in kind, than the feelings of affection one has for others" (Brown & Dutton, 1995, p. 712). More complex are models of self-esteem as a "combination of cognitions and evaluations of many attributes of self" (Wylie, 1979, p. 4), as "a fraction of which our pretensions are the denominator and the numerator our success" (James, 1890, p. 310), as a difference "between an individual's ideal and actual concepts of himself" (Cohen, 1959, p. 103), as "the component of the self-system which regulates the extent to which the self-system is maintained under conditions of strain" (Ziller, Hagey, Smith, & Long, 1969, p. 84), and as "the feeling that one is an object of primary value in a meaningful universe" (Greenberg et al., 1992, p. 913).

Functions of Self-Esteem

Despite wide endorsement of the importance of self-esteem, there is substantial variation in theoretical conceptions of *how* self-esteem functions in ways that justify its status as an essential ingredient of personality. The first of three categories of functional views includes those that postulate a *protective or defensive* function. The nature of how a threat is conceived varies, including (1) threats to social acceptance (sociometer theory), (2) negative consequences of achievement failure (affect regulation model of self-esteem functioning), or (3) the prospect of death (terror management theory).

A second category of theories proposes *self-promotive* functions. These include: (1) self-determination theory's view that positive self-esteem fulfills needs for competence, relatedness, and autonomy, (2) self-actualization theory's view that self-esteem is a learned human need, which, once met, paves the way for satisfaction of higher-order needs such as self-actualization, and (3) humanistic personality theory's view that self-esteem serves a need for unconditional positive regard.

A third category of theories postulates that self-esteem serves an *identity-maintenance* function. These include: (1) social identity theory's view that low self-esteem motivates identification with positively regarded groups, (2) self-affirmation theory's view that high self-esteem provides a resource to affirm a threatened identity in an alternative domain, (3) self-verification theory's view that people seek to maintain stable and coherent self-views (identities), and (4) balanced identity theory's view that identities, attitudes, and self-esteem tend to self-organize on principles of affective–cognitive consistency.

Defensive and promotive functions of self-esteem can be seen as homeostatically linked, with the defensive function sustaining self-esteem at a level high enough for promotive functioning to be effective. The identity-maintenance function also suggests that self-esteem is acting homeostatically. Thus, all three types of function are consistent with a higher-order theme that self-esteem serves a personality-stabilizing function.

Predictive Validity of Self-Esteem

The uniformity of these views in treating self-esteem as a desirable trait makes it somewhat surprising that none of the theories of self-esteem function has an accompanying conclusive body of supporting empirical research. An extensive literature review by Baumeister, Campbell, Krueger, and Vohs (2003) concluded that predictive validity of self-esteem measures with respect to psychological health, well-being, school achievement, and occupational success, is generally very modest at best, with the majority of variance in these indices left unaccounted for: High self-esteem does not cause better academic performance, occupational success, or leadership (nor does low self-esteem cause aggression, tobacco/alcohol use, or becoming sexually active at an early age). This lack of strong predictive validity of self-esteem for positive outcomes suggests that the benefits of high self-esteem may be fewer and weaker than personality psychologists such as Rogers and Allport had conceived.

Implicit Measures of Self-Esteem

Some of the weakness of empirical evidence for the various theories is almost certainly due to limitations of available measures of self-esteem. The most widely used self-esteem measures are highly transparent sets of self-report items, for which most respondents will know that they are responding to an assessment of some aspect of self-positivity. Widespread understanding that self-esteem is a desirable trait assures that these transparent measures will assess a mixture of self-positivity and impression management. For example, the estimates of contamination by impression management for the Rosenberg Self-Esteem Scale range between .26 and .45 in terms of correlations with social desirability and self-deception.

A more recent development in assessing self-esteem that may avoid self-presentational distortion is use of the Implicit Association Test (IAT). It has been found that IAT measures of self-esteem correlate quite weakly with self-report measures of self-esteem. However, there is no strong reason to expect implicit and explicit measures of self-esteem to be more than weakly correlated, and discrepancies between explicit and implicit self-esteem may be meaningful and of theoretical importance.

Disappointingly, implicit measures of self-esteem correlate weakly with one another. A likely explanation of this weak intercorrelation is in psychometric weaknesses in most of the available implicit measures. However, among implicit measures, the IAT has the highest test–retest reliability and the best temporal stability over a four-week period.

A notable exception to the observation of predictive validity problems for self-esteem measures is the substantial body of theoretical confirmations of predictions of balanced identity theory (BIT; Greenwald et al., 2002) from studies that have used IAT self-esteem measures. According to BIT's *balance–congruity* principle, the association between two concepts should strengthen when both concepts are associated with the same third concept. For people who already associate self with *good*, associating a *group* with *good* should lead to the development

of an additional association between *self* and that *group*. One resulting prediction is that those high in self-esteem will identify with their in-group more than will those low self-esteem. In research testing BIT's balance–congruity principle, confirmations have been obtained consistently with IAT self-esteem measures, while results with parallel self-report self-esteem measures do not reveal the theoretically expected patterns (Cvencek, Greenwald, & Meltzoff, 2012).

Self-Esteem in Children

Developmental scientists investigate the origins, causes, and developmental progression of self-esteem. Important work on young children's self-evaluations has been done by Harter and colleagues using picture identification and self-report. Harter has found that young children (ages 3–7) can evaluate themselves in terms of *particular* cognitive abilities ("I know the alphabet"), physical abilities ("I can tie my shoes"), their appearance ("I am happy with the way I look"), and other specific characteristics. Findings show that these domain-specific self-evaluations are highly positive for the majority of young children, agreeing with social psychology research showing that the vast majority of adults have a positive attitude toward self.

Harter and colleagues have described difficulties in investigating self-esteem in preschool children. Owing either to cognitive limitations or to limitations of available measuring instruments, young children show no evidence of integrating the domain-specific self-evaluations into a higher-order, overall evaluation of themselves. Children apparently cannot verbally report on their global self-esteem, but only on their self-concepts in particular areas (such as math, physical achievements, etc.). This limitation does not dictate that they lack a global form of self-esteem. It has been hypothesized that, although young children are unable to demonstrate global self-esteem in self-report, it nevertheless is manifest in their *behavior*. Using a Q-sort method with experienced preschool teachers, researchers have identified behaviors that are interpreted as reflecting levels of global self-esteem in preschool children (e.g. displays of confidence, curiosity, and independence).

Indirect measures (ones not relying on self-report) are used increasingly by developmental psychologists. To measure preschool children's self-esteem, recent studies have adapted the IAT to measure self-esteem without relying on self-report (Cvencek, Greenwald, & Meltzoff, 2016). This has permitted investigations that compare roles of implicit and explicit self-esteem in children, revealing now that self-esteem – when measured implicitly but not when measured by self-report – is evident in children as young as 5 years of age, who display affective–cognitive consistency of the same type previously demonstrated for adults.

Self-regulation

Kristi Chin[1] and Sarah C. E. Stanton[2]

[1] *University of Michigan*
[2] *University of Edinburgh*

Introduction: What is Self-Regulation?

Self-regulation is a psychological process through which people bring their behavior and cognition in line with their goals, and is marked by effortful and voluntary control. For self-regulation to be successful, one must (1) be aware of their actions and thoughts and (2) have the capacity to control and change them in the face of external, internal, or environmental influences.

The general organizing framework of self-regulation begins with foundations, extends to Type 1 and Type 2 processes, and ultimately reaches goal-related activity. *Foundations* refer to basic tendencies that are part and parcel of self-regulation, and include executive function, temperament, and personality. Executive function is the skill and capacity that allows people to engage in planning, decision making, error correction, and inhibition. Temperament involves individual differences in reactivity that are expressed through emotional, motor, and attentional domains. Finally, personality comprises the patterns of behavior and cognition that are consistent over time and situations, and also reflects individual differences in strength and sensitivity of dispositions. These foundations can influence goal-related activity for self-regulation directly or indirectly via Type 1 and Type 2 processes.

Type 1 processes are described as self-regulation that occurs across time and situations in pursuit of long-term goals. This includes forethought/planning, whereby people set goals and make plans to achieve them. Type 1 processes also include performance, which refers to exercising self-control for the purpose of long-term goals. Lastly, people scrutinize their behavior and reflect on whether it matches their goals during monitoring/self-reflection. In contrast, *Type 2 processes* are described as self-regulation for short-term goals. Type 2 processes include self-monitoring, whereby people monitor their behavior and address any disruptions in their goal pursuit. People can also determine whether their behavior is goal-related during self-evaluation. Finally, people reinforce goal-related behavior in a positive or negative manner.

In *goal-related activity*, a goal is initiated and leads to self-regulatory behaviors and thoughts. For example, imagine that Beverly desires to lose 10 pounds before her son's wedding in a few months, and has decided that today is the day she starts working toward that goal. Following initiation of the goal, Beverly would next make assessments whereby she compares her self-regulatory goal and the means to achieving that goal, yielding specific planning (e.g. exercising daily, avoiding junk food). The subsequent pursuit of Beverly's goal requires persistence, maintenance, and self-monitoring in the face of internal and external challenges (e.g. successfully avoiding junk food even when she craves it or it is offered). If Beverly evaluates herself and feels her current behavior is incompatible with her goal, she can use locomotion to move from her current state to another state (e.g. packing a healthy lunch instead of eating out with co-workers). In addition to active goal pursuit behaviors, Beverly's effective self-regulation also allows her to disengage from those behaviors if her goal becomes irrelevant or is achieved.

The capacity for people to engage in self-regulation can be conceptualized as a continuous dispositional variable. People with higher dispositional self-control tend to be more self-efficacious, are better able to achieve their goals, and have more successful careers and relationships. Conversely, persons with lower dispositional self-control tend to be more impulsive, have difficulty persisting in goal pursuit, and often experience less career and relationship success.

Moreover, there are two behavioral styles that help explain self-regulation as personality. First, *behavioral inhibition* reflects the capacity to control actions through restraint. People who commonly use behavioral inhibition are sensitive to punishment and are prone to anxiety and avoidance, and there is typically a prevention focus; that is, an emphasis on avoiding negative outcomes and prioritizing responsibility and duty. Second, *behavioral approach* reflects the capacity to perform actions relevant to achieving self-regulatory goals. People who use a more behavioral approach are sensitive to reward and are prone to impulsivity and novelty-seeking, and there is typically a promotion focus; that is, an emphasis on attaining positive outcomes and prioritizing growth and achievement.

Five Factor Model and Self-Regulation

People can use different forms of self-regulation, and these different forms are associated with the Five Factor Model of personality. People with higher scores on openness to experience, extraversion, and agreeableness tend to use a behavioral approach style of self-regulation, and people higher in extraversion and agreeableness tend to make group or co-operative goals. The most successful self-regulators, however, are people higher in conscientiousness. More conscientious people are known for their effort expenditure, persistence, and efficient use of time and are excellent self-regulators because they monitor their behavior and manage their time and environment.

On the other hand, people higher in neuroticism scores tend to be particularly unsuccessful self-regulators. Neurotic people tend to use behavioral inhibition to self-regulate but lack control and are unable to direct their behavior to effectively pursue goals; thus, more neurotic people tend to fail at self-regulating. People who are lower in neuroticism and high in conscientiousness are successful at self-regulating because they understand their goals and are able to effectively work toward them, even in adverse conditions.

Self-Regulation Failure

When is self-regulation *un*successful? Researchers have identified several major threats to effective self-regulation. The most frequent reason people use self-regulation is to control their impulses (e.g. a chocolate advertisement may trigger an impulse in Beverly to buy and consume chocolate). Sometimes impulses lead people to give in to temptation, however, sometimes exposure to stimuli that would typically lead to impulsive behavior yields an *increase* in effective self-regulatory behavior. This effect occurs most often when people have a history of successful self-regulation while exposed to relevant temptation. In this case, the stimulus that triggers an impulse also activates motivation and strategies that work toward self-regulatory goals.

In addition to external stimuli that threaten self-regulation, experiencing internal feelings of emotional and/or social distress can undermine effective self-regulation. For instance, when people experience negative emotions they are less likely to delay gratification and also experience reduced working memory, which undermines the monitoring process inherent in self-regulation. Sadly, a vicious cycle often emerges wherein negative emotions undercut working memory, and diminished working memory then induces more negative emotions. Common social situations that can trigger negative emotions include social rejection or stereotype threat.

Self-regulation also often fails because of a phenomenon known as *lapse-activated patterns*, where giving in to a single temptation leads to total disinhibition and abandonment of self-regulatory goals and produces further lapses in self-regulation. For example, Beverly may give in to her chocolate-craving impulse and eat one piece of chocolate, but before she knows it she has eaten the entire box and opened another. Lapse-activated patterns are frequently explained by the *abstinence violation effect*; people react to self-regulation failure with feelings of despair, guilt, and personal let-down. Unfortunately, people are likely to experience additional lapses in self-regulation with this combination of negative emotions and beliefs about personal failings.

The presence of others has an enormous capacity to influence successful self-regulation as well. For instance, *deindividuation* refers to the phenomenon whereby people lose their sense of individual identity when they are in a group. Being part of a group enhances feelings of anonymity and reduces self-awareness, which together lead to self-regulation failure. If Beverly feels more anonymous at a group dinner party, she may feel less accountable for her actions and more likely to engage in counter-goal behavior (e.g. consuming junk food). Other people may further influence self-regulation by exhibiting behavioral norms that are not aligned with one's self-regulatory behaviors. For example, if everyone at the dinner party is eating at least two pieces of cake for dessert, Beverly may be more likely to follow suit, a failure in her pursuit of her self-regulatory goal.

Situational variables, such as the psychological resources available, also influence self-regulation success. The strength model of self-regulation suggests that people have limited psychological "willpower" resource that is used to enact self-regulatory behavior. When one's self-regulatory capacities are tapped, often by engaging in self-regulation, they enter a state of *ego depletion* wherein they temporarily possess fewer psychological resources to exert willpower should they need to engage in additional self-regulation, and thus, lead to self-regulatory failure.

Finally, alcohol intoxication is one of the strongest threats to self-regulation. Alcohol leads to self-regulation failure by reducing self-awareness, impairing the capacity to inhibit counter-goal behaviors, and decreasing the ability to notice self-relevant cues and obtain evaluative feedback. Moreover, alcohol increases the appeal of and desire for rewards. Failure in self-regulation associated with alcohol intoxication, nonetheless, occurs only when there are strong instigating pressures (e.g. Beverly has multiple drinks because every-one else at the dinner party is doing so).

In sum, self-regulation refers to the process of controlling thoughts, feelings, and actions to manage short- and long-term goals. People exhibit individual differences in their dispositional capacity to effectively self-regulate and the self-regulatory strategies they use, and the process of self-regulation is also meaningfully related to core established personality variables in the Five Factor Model. There are, however, a number of external or internal factors that can cause self-regulation to fail, including experiencing negative affect and/or reduced self-awareness, the presence of others, being in a state of ego depletion, or alcohol intoxication. Understanding threats to self-regulation, practicing small acts of self-control, and increasing self-awareness can improve the overall ability to effectively self-regulate. To be sure, the process of self-regulation is important to understand through the lens of personality and individual differences.

Sensation Seeking

Marco Giannini and Yura Loscalzo

University of Florence, Department of Health Sciences, School of Psychology

Definition

The relevance of the construct of sensation seeking is suggested by the extensive scientific literature on this topic. At the beginning of 2016, entering "sensation seeking" as keyword in PsycINFO, there were more than 4,000 publications. In addition, PsycINFO reported 207 publications in academic journals only for the year 2015.

Sensation seeking, as defined by Zuckerman in 1994, is a personality trait characterized "by the seeking of varied, novel, complex, and intense sensations and experiences, and the willingness to take physical, social, legal, and financial risks for the sake of such experiences." This definition implies that the high-scoring individual pursues activities which could be associated with some degrees of risk, but that risk is not the determinant of the behavior itself. The risk is a possible consequence of the behavior enacted, and the individual accepts it in order to reach the desired level of arousal. Zuckerman preferred the term "sensation" instead of "stimulation," since the reinforcement for the behavior is manifested in the sensory effect produced by the stimulation. Indeed, the high sensation seeker looks for external stimuli that heighten the chance of experiencing internal sensations. Moreover, Zuckerman pointed out that "seeking" is used in order to highlight that the construct reflects an active mode; if sensation seekers are in the sensory deprivation condition, they are able to stimulate themselves (e.g. whistling or producing vivid fantasies).

More specifically, sensation seeking comprises four dimensions:

- *Thrill and adventure seeking*, namely the desire to take part in activities that involve physical risk (e.g., mountain climbing, scuba diving);
- *Experience seeking*, that is looking for new personal or inner experiences (e.g., exploring an unknown city alone, trying hallucinogenic drugs, trying new foods);

- *Disinhibition*, which refers to social and sexual activities characterized by disinhibition (e.g., enjoying the company of swingers, drinking liquor, or smoking marijuana to get high);
- *Boredom susceptibility*, or intolerance of activities that are repetitive (e.g., getting bored seeing the same faces, not enjoying a movie whose plot can be predicted in advance).

The Sensation Seeking Scale form V (SSS-V) is the most commonly used self-report instrument for assessing sensation seeking and these four components. It includes 10 items for each scale, for a total of 40 items. There are two sentences (A and B) for each item, and the subject indicates which of the two is most representative of him/her. Zuckerman developed the first form of the SSS in the 1960s in order to use it in an experiment regarding sensory deprivation; the scale was based on the idea that people can have different optimal levels of stimulation and arousal, which in turn could affect their activities.

Other instruments used to evaluate this construct are the Impulsive Sensation Seeking subscale of the Zuckerman-Kulman Personality Questionnaire (ZKPQ) and the Arnett Inventory of Sensation Seeking (AISS). The ZKQP consists of 99 true-false items and is scored on six scales: Impulsive Sensation Seeking, Neuroticism-Anxiety, Aggression-Hostility, Sociability, Activity, and Infrequency. The first scale, the one specifically for measuring sensation seeking, is made up of 19 items addressing the need for thrills and excitement, preference for unpredictable situations and friends, and the need for novelty and change. The AISS includes 20 items and has two scales (Intensity and Novelty); it asks subjects to indicate by means of a 4-point Likert scale their agreement with each item. A prominent feature of both the Impulsive Sensation Seeking scale of the ZKPQ and the AISS is the lack of any reference to specific sensation seeking activities; these, in contrast, are present in the items of the SSS-V.

Sensation Seeking and Impulsivity

Sensation seeking and impulsivity are two different constructs. In earlier literature, sensation seeking was described as a component of impulsive behavior; however, they are two different constructs. More specifically, impulsivity refers to a predisposition toward rapid and unplanned reactions to stimuli (either internal or external), with few or any considerations of the negative consequences that the enacted behavior could have for oneself or others. In addition, impulsivity is characterized by a decrease from childhood to adulthood; this decrease is most significant during adolescence, probably because of the maturation of the cerebral areas devoted to the cognitive control. In contrast with impulsivity, sensation seeking shows a linear increase from early to middle adolescence. It has a different developmental trajectory compared to impulsivity, supporting that they are two different constructs.

Biological Correlates of Sensation Seeking

Sensation seeking is a personality trait whose biological correlates have been widely studied, in particular with regard to the neuroendocrine and gonadal systems.

There is evidence that sensation seeking (especially the components of disinhibiting behavior preference and experience seeking) is correlated with low levels of cortisol (i.e., stress hormone) and hence with a high stress resilience. Moreover, low levels of cortisol could lead to increased activity in the dopamine systems and to decreased activity in the serotonergic systems. However, there are contrasting findings about neuroendocrine response between human and animal studies, suggesting the need for major research on this area. With regard to the gonadal system, some studies found a positive correlation between the disinhibiting behavior factor of sensation seeking and androgen and estrogen levels in males, as well as with levels of follicular and luteal estrogens in females.

Sensation Seeking and Demographic Differences

Some demographic variables have been analyzed with regard to sensation seeking, including age, gender, and culture. As regards age, there are no significant differences in sensation seeking between 16 and 20 years, while there is a subsequent decline from age 20. Another difference in sensation seeking scores emerges in relation to gender. Males report higher scores than females on three of the four scales of the Sensation Seeking Scale (i.e., Thrill and Adventure Seeking, Experience seeking, Disinhibition, Boredom susceptibility). More specifically, there is no gender difference on the Experience seeking scale, and the greatest difference is on the Disinhibition scale. Some studies have also compared Black and White college students, showing that the Disinhibition scale is the only one of the four that does not show significant differences between the two groups.

Some Characteristics of High Sensation Seekers

People high on sensation seeking are characterized by a great deal of tolerance for high intensity and painful stimuli, and by a high level resilience to negative stressors. Moreover, high sensation seekers appraise many situations as less risky than low sensation seekers do; this could explain their propensity to engage in risky activities. They also seem to process information efficiently, however, this does not guarantee high levels of school achievement. Another cognitive characteristic of high sensation seekers is a tendency to accept as true ideas that do not have any theoretical foundation and which are merely speculative. Finally, they prefer visual stimuli that are complex over simple and symmetrical ones. In the area of attitudes, high sensation seekers are characterized by permissive attitudes regarding sexuality and political liberalism, namely the tendency to prefer immediate change with less concern for consequences for the social order.

Negative and Positive Behaviors Correlated with High Sensation Seeking

The arousal theory suggests that when an individual experiences physiological under-arousal as unpleasant, he/she will engage in behaviors directed at increasing the level of arousal. However, high sensation seeking individuals can choose various activities in order to reach the desired level arousal; these activities can be either positive or negative.

For example, there are people that engage in negative activities with high risk, such as high-risk sports, gambling, risky driving, risky sexual behaviors, and excessive use of alcohol or drugs. However, other people can channel their need for sensation seeking into the choice of a job that can satisfy this need; thus, they prefer occupations that involve novel situations, flexibility, and unstructured tasks. More specifically, males with high levels of sensation seeking are interested in jobs that require personal interactions, while they avoid business and clerical jobs. On the other hand, high sensation seeking females tend to reject historically typical female occupations such as teaching or being a housewife. Finally, with regard to high-risk occupation (e.g., law enforcement, aviation), there seems to be an association between these jobs and scores on the Thrill and Adventure Seeking scale, and not the general level of sensation seeking. In addition to occupational choice, some other individuals appear to satisfy their need for high arousal by means of other positive activities such as hard rock music, high impact sports (i.e., rock climbing or parachute jumping) or traveling. It is interesting to note that people with levels of high sensation seeking are also more likely to volunteer for research experiments that involve drug taking, sensory deprivation or hypnosis, since these activities are associated to new and unusual experiences. Thus, while the literature highlights how many negative behaviors are correlated with high levels of the sensation seeking trait, there are also some positive behaviors correlated with it.

As pointed out by Norbury and Husain (2015), it is important to consider the key role of the environment in influencing the specific behaviors that the individual will pursue in response to his/her high level of sensation seeking. Families with a high socio-economic level may have the possibility of making available for their sons and daughters socially acceptable behaviors and outlets, such as travels and adventure sports. On the other hand, families with a low socio-economic level may not be able to provide such opportunities, so that risky, antisocial or criminal activities could be the only choice provided by the environment. Indeed, even if there is a strong genetic basis for the expression of sensation seeking, social factors could also have an influence on it. For example, parents with high sensation seeking, compared to low-sensation-seeking parents, could be more likely to offer more stimulating situations to their children and might be more likely to stimulate autonomy in their children as well. Most likely, social and genetic influences interact in contributing to the expression of the sensation-seeking trait.

Sensation Seeking and Psychopathology

With regard to psychopathology-related research, a large number of studies are related to addictions: substance-related addictions, such as alcohol, tobacco, marijuana, or cocaine, as well as behavioral addictions, such as internet addiction or gambling. However, there are many other behaviors that do not reflect a diagnostic category that have also been analyzed with regard to their relationships with the sensation seeking construct (such as risky driving). Adolescents and youths are the most studied populations, given the increase in risky behaviors typical of these ages.

In analyzing the relationship between sensation seeking and specific problem behaviors, it should be kept in mind that there may possibly be different correlations between the same behavior and the four sensation seeking components proposed by Zuckerman.

For example, regarding risky driving (such as tailgating too closely or driving while impaired) many studies found a positive relationship between risky driving and sensation seeking, especially the Thrill and Adventure Seeking dimension. In contrast, the dimension most correlated with alcohol use is Disinhibition. In addition, we have to bear in mind that sensation seeking is only one of many different traits that interact to predispose someone to the development of a clinical disorder; not everyone with high sensation seeking will develop a clinical disorder.

Shyness

Bernardo J. Carducci and Kristina C. Conkright

Indiana University Southeast

Shyness Defined

Shyness can be defined by the presence of anxious reactions and excessive self-consciousness and negative self-evaluation in the response to real or imagined social interactions to the degree that it produces enough discomfort to interfere with and inhibit one's ability to perform successfully in social situations, often to the extent that it can also disrupt the fulfillment of one's personal and professional goals. The affective/physiological component of shyness reflects the anxiety, muscle tension, increased heart rate, upset stomach, and an assortment of other psychophysiological reactions experienced by shy people. The cognitive component of shyness reflects the excessive sense of self-consciousness (e.g. Everybody is staring at me), negative self-appraisal (e.g. What I said was so stupid), irrational belief system (e.g. Nobody at the party will find me interesting) characteristic of the way that shy people think about themselves. The behavioral component of shyness is expressed by behavioral inhibition (e.g. not speaking to others at a party) and social avoidance (e.g. avoiding eye contact or standing in the corner during a group discussion). Individuals expressing the trait of shyness also demonstrate a slow-to-warm tendency characterized by an extended period of adjustment to social, especially novel, situations. In contrast to shyness as a trait, the state of situational shyness is the transitory experience of the characteristic features of shyness that can be triggered by a variety of situations, with the most frequent being interactions with authorities, one-to-one interactions with members of the opposite sex, and unstructured social settings.

Pervasiveness of Shyness

A consistent pattern of culture-specific estimates of shyness is the large percentage of participants in those cultures surveyed who reported experiencing shyness – from 31% in Israel to 57% in Japan and 55% in Taiwan. A more moderate rate of approximately 40% of

participants in the United States who reported experiencing shyness is similar to those participants surveyed in Canada, Germany, India, and Mexico.

Measurement of Shyness

The most frequently used measure of shyness is the Revised Cheek and Buss Shyness Scale (RCBS). The RCBS contains 20 items assessing the three principal dimensions of shyness: affective/physiological (e.g. "I feel tense with people I don't know"), cognitive (e.g. "I feel painfully self-conscious when I am around strangers"), and behavioral (e.g. "it is hard for me to act natural when I am meeting new people").

Subtypes of Shyness

Subtypes of shyness reflect the manner in which shy individuals express their symptoms of shyness. Expressions of shyness by publicly shy individuals tend to emphasize the behavioral component of shyness, such as being too quiet (e.g. not participating in a conversation), behaving awkwardly (e.g. avoiding eye contact or keeping an extended personal space from others), and failing to respond appropriately in social situations (e.g. not acknowledging a compliment). Expressions of shyness by privately shy individuals tend to emphasize the affective component of shyness, such as through intense psychophysiological arousal (e.g. pounding heart, muscle tension, and anxiety reactions). Expressions of shyness by socially anxious shy individuals tend to emphasize the cognitive component of their shyness, such as being excessively self-conscious (e.g. "Do my clothes fit right?") and overly concerned about being evaluated socially by others (e.g. "I wonder what she thinks of my comment?"). The identification of the different types of shyness also has implications for their treatment.

Similarities of Shyness to Other Constructs

Although similar in their overt expression (e.g. remaining at the periphery at social gatherings), introversion and shyness are not interchangeable constructs. Introverts, like extraverts, do not fear social situations, but simply prefer more sedate, solitary activities, and gravitate toward the periphery of social situations as an expression of this preference. Shy individuals, similar to extraverts, express a desire to be with others and demonstrate a tendency to seek out social situations to be in the proximity of others in an attempt to meet this desire but are inhibited in their efforts to interact with others by their excessive self-consciousness, negative self-evaluation, and perceived lack of social skills (e.g. inability to initiate and maintain conversations), and, unlike extraverts but similar to introverts, gravitate toward the periphery of social situations. Social anxiety disorder (also referred to as social phobia), which is experienced by approximately 12% of the U.S. population, involves the experience of anxiety and self-critical evaluation in social settings in response to the fear of evaluation of one's public performance (e.g. speaking to a crowd) by others and a

greater disruptive influence on one's social behavior to a degree beyond that of the experience of shyness (e.g. avoid going to parties). Unlike the experience of shyness, more extreme expressions of social anxiety disorder involve feelings of anxiety and excessive critical self-evaluation to such a heightened degree that it can serve to have a much more pervasive and disruptive influence in (e.g. signing a check, talking on the telephone, or using a public restroom) and the avoidance of (e.g. eating in public, getting on public transportation, or going to the movies) a variety of everyday situations.

Explanations of Shyness

Explanations of shyness include both biological and psychological contributions, as well as their interaction. Biological contributions to shyness include elevated levels of certain stress hormones (e.g. cortisol). Genetic explanations of shyness in early childhood focus on the inherited temperament of high reactivity, which is characterized during infancy by an excessive reaction (e.g. excessive crying and vigorous movement of the head and limbs for a prolonged period of time) in response to novel sources of stimulation (e.g. loud noises, strong smells). High reactive infants also display a greater degree of behavior operationally defined as timid but frequently referred to as "acting shy" (e.g. playing near the primary caretaker) and characterized by social avoidance (e.g. running and clinging to the primary caretaker when a stranger enters the room) during early childhood and experience more problems with anxiety during adolescence. Neurological explanations of shyness focus on individual differences in certain brain structures associated with the acquisition of the emotional responses of fear and anxiety, such as the bed nucleus of the striate terminals, the amygdala, and hippocampus, through the process of classical conditioning. It is suggested that due to their greater degree of sensitivity, highly reactive individuals condition fear and anxiety responses to a greater degree and to a wider range of social situations than less reactive individuals, resulting in the manifestation of a more limited comfort zone. The evolutionary benefits of shyness include cautionary behavior in novel and potentially threatening situations and the facilitation of social exchange and co-operation through the reduced tendency for self-serving expression.

Environmental factors associated with explanations of shyness include overprotective parenting styles that foster a lowered level of frustration tolerance for anxiety and stress when developing social skills through play during early childhood (e.g. parents taking over the play activity). Self-report causes of shyness include inability to make friends due to frequent moves by one's family, embarrassing experiences in school during childhood (e.g. being teased, bullied), and failure to learn social skills due to parents not socializing with other families. Explanations based on the interactionist account of shyness suggest that certain biological factors (e.g. inhibited temperament) combined with certain family dynamics (e.g. overprotective parents) contribute a more fearful reaction of social situations due to a reduced sense of self-confidence as a result of the child not being permitted to master the social skills during childhood that are necessary for navigating the more complex social situations encountered during adolescence and adulthood. However, it should be made very clear that the complexities of shyness have made it difficult to provide a clear and definitive answer to the question of "What causes shyness?"

Culturally based explanations of shyness suggest that those personality factors associated with shyness, such as lowered self-perceived interpersonal competencies and expectations of rejection, are experienced to a greater degree in Asian cultures, which tend to be more collectivist and promote the esteem of the group and place greater restraints on individual expression, than in Western cultures, which tend to be more individualistic and allow for greater ease and tolerance of individual expression.

Dealing with Shyness

Although shyness is not considered a psychiatric disorder, the experience of shyness can create sufficient affective discomfort and problems in the personal lives of shy individuals that they will seek professional assistance to deal more effectively with their shyness. Approaches to helping shy individuals deal more effectively with their shyness also tend to reflect a "cultural fit" that focuses on cross-cultural differences between Eastern and Western cultures. Consistent with Eastern (i.e. Asian) values and social structure, Morita therapy, which is based in the Buddhist perspective, focuses on helping individuals to change their inner attitudes (e.g. others will discover publicly their faults) and behavioral expectations (e.g. behaving foolishly in public) to foster greater adjustment and effectiveness without altering the symptoms (e.g. acknowledging and accepting feelings of anxiety in social situations). Morita therapy emphasizes that shy individuals be more accepting of the symptoms of their shyness (e.g. It's OK. to have feelings of anxiety and uncertainty) and less critical of their actions (e.g. worry less about whether or not a joke was funny enough).

In Western cultures, the emphasis on independence and the self-expression through more direct communication and a greater tolerance of self-promotion raise concerns for developing a more valued interpersonal style characterized by extraversion. To deal with the affective component of shyness, progressive relaxation and biofeedback techniques focus on the reduction of bodily arousal to minimize the impact of anxiety during the execution of social behaviors. To deal with the cognitive component of shyness, cognitive-modification techniques attempt to revise self-perceptions, alter attributions, and adjust expectations for defining success while performing in social situations. To deal with the behavioral component of shyness, programs for promoting interpersonal exchanges focus on the acquisition and development of social skills such as strategies for approaching others, techniques for initiating and maintaining conversation, and procedures for entering on-going conversations. Structured clinical programs typically involve combining elements from all of the approaches, such as using cognitive modification to identify what situations produce the most critical self-evaluations and structured role-playing exercises within the context of systematic desensitization to reduce anxiety while teaching appropriate behavioral responses and building self-confidence in those situations. In the United States, an emerging controversy in the treatment of shyness is the medicalizaion of shyness by attempts to link it with more serious psychiatric conditions, such as social phobia, and emphasize its treatment by the use of prescription drugs including those based on selective serotonin reuptake inhibitors (SSRIs).

16PF, Correlates of

Emily R. Bunnett

Swinburne University of Technology

The 16 Personality Factor Questionnaire (16PF) is one of the most widely used measurement tools for assessing personality in non-clinical psychological and organizational domains, providing a thorough analysis of the entire range of personality factors. The scale has been developed over the past nine decades using a form of factor analysis termed parcel analysis, with each successive revision aiming to further validate and standardize the measure, alongside ensuring that the item content and scale interpretations are current. Cattell's main aim throughout this process was to identify and assess the rudimentary structural elements of personality. Furthermore, these factor analytic procedures provided evidence for his proposed multi-level, hierarchical model of personality, with a three-level model providing the best fit for analysis of the full range of personality traits (i.e. with 16 primary, five second-order and two third-order factors) in successively broader and conceptual terms. Specifically, interpretation of the primary factors enables the formation of a more detailed, precise, and unique personality profile, whereas assessment of the second-order or global five factors of personality results in a broader or more general view of one's personality. Nevertheless, there is only preliminary evidence postulating the presence of two third-order factors, denoting the most abstract assessment of personality and the highest level of the hierarchical model, hence the exact nature of these tertiary scales requires further research (Cattell & Mead, 2008).

Development and Structure of the 16PF

Cattell and colleagues developed the 16PF on the premise that all important, useful and interesting components of personality were already documented in language, thus rather than employing a theoretical standpoint for the basis of scale development and foundation, they systematically sampled and assessed all relevant terms in a large-scale factor analysis. They originally proposed 20 primary factors, however, four factors were very poorly defined and hence these were removed to provide a final solution that was easily interpreted, showed simple structure, and was consistently reproduced across varied samples from diverse

cultural, ethnic, educational and socio-economic groups. Furthermore, since the publication of the first edition in 1949 the scale has been translated and adapted into 35 languages through ongoing collaboration with researchers around the world (Cattell & Cattell, 2016).

The fifth and latest edition of the 16PF aimed to (1) refine and simplify item content and length, (2) reduce or avoid the presence of any biases associated with gender, disability, or ethnicity and of socially desirable and undesirable content (for use in organizational settings) and (3) increase factor loadings and interpretability. In contrast to previous versions of the measure, the latest revision only presented one form, persisting of items refined through a four-stage iterative process, from an item pool consisting of updated versions of the best items from the five forms of the fourth edition and newly formed items. The latest version appears to be more psychometrically sound than previous editions, improves hand scoring techniques and displays factor loadings, structure and psychological interpretations that align with the previous versions of the measure. The current version appears to display factor validity and good internal reliability (*median* = 0.75) and test–retest reliability over a two-week period (*median* = 0.80), despite critics noting that the authors' focus on criterion-related validity at the expense of internal consistency jeopardized the psychometric value of the study (Cattell & Cattell, 2016).

Similarly, prior respondents' concerns regarding the ambiguous nature of item-specific middle response options (i.e. varying across items) was addressed through the implementation of a standardized middle response. Specifically, the current version implements "?" as the middle response option, with the two extremes representing a positive and negative option for each trait. The items are scored 0 (negative option), 1 (?) and 2 (positive option). The use of successive integers to score the response options infers that the middle response represents an intermediate presence of the trait. Nevertheless, research has indicated that participants employ "?" to represent several disparate forms of responding which commonly contradict the inferred meaning of the response and result in category disordering or category threshold disordering (Murray, Booth, & Molenaar, 2015). Alternatively, respondents may employ the middle response to represent that they are "uncertain" or feel that the item is "not applicable" to them.

The fifth edition comprises 185 items, written at a fifth-grade reading level, investigating one's daily behavior, interests, and opinions. The questionnaire was developed for respondents aged 16 years or older. The scale scores are presented as stens, enabling easy interpretation of one's standing relative to normative data (with a standardization sample of over 10,000). Scores are provided on the 16 primary, five global personality and three response bias scales. All scales are bipolar, with both ends being coherently defined and providing meaningful descriptions. The bipolar operationalization of scales provides one important distinction between the 16PF and alternative measures of the five global factors of personality. Nevertheless, factor analyses employing various measures and models of these broad factors indicate that they tend to display comparable factor structures, providing parallel measures of the same underlying personality traits (please see Cattell & Mead, 2008, for more detail).

Primary and Secondary Traits

The following section describes each broad factor in turn, along with the primary factors that they encompass (e.g. Conn & Rieke, 1994).

Extraversion/Introversion

The extraversion/introversion scale provides an index to the degree to which one is socially oriented (extroverted) versus inhibited (introverted). This scale comprises five primary scales.

Warm-Reserved (A). The warm-reserved primary scale measures how friendly a participant is and how willing they are participate in social activities and contexts. High scorers are described as warm, caring, attentive to others and contributors in interpersonal settings. Low scorers are generally described as aloof, impersonal, distant, reserved and detached.

Lively-Serious (F). This scale indicates how expressive and cheerful one is compared to how introverted and serious. High scorers are described as lively, expressive, enthusiastic, animated, and cheerful, whereas low scorers tend to display restrained, cautious, serious, taciturn, silent and introspective characteristics.

Bold-Shy (H). The bold-shy scale displays the degree to which one is uninhibited and outgoing versus timid and shy. High scores indicate social boldness, venturous natures, while low scores signify threat-sensitive, timid personas.

Private-Forthright (N). This primary personality scale measures how forthright or private a person tends to be. High scores indicate private, discreet, astute, and diplomatic tendencies and low scores genuine, forthright, unpretentious, open and naïve tendencies.

Self-Reliant-Group Oriented (Q2). This scale signals how group oriented or self-sufficient an individual is. High scorers are often described as solitary, individualistic and resourceful, whereas low scorers are commonly considered followers, affiliative dependent, and group oriented.

High Anxiety/Low Anxiety

The global anxiety factor indexes how perturbable or unperturbable one is, encompassing four primary trait scales.

Emotionally Stable-Reactive (C). The primary emotionally stable-reactive personality factor measures how easily participants respond to stress and how emotionally liable they are. High scorers are seen as adaptive, emotionally stable, and mature, while low scorers are considered emotionally liable, affected by feelings and reactive.

Vigilant-Trusting (L). This scale signifies how vigilant or suspicious versus trusting and accepting one is around other people. High scorers are described as vigilant, skeptical, and wary. Low scorers are described as unsuspecting, trusting, accepting, and unconditional.

Apprehensive-Self-Assured (O). Apprehensive-self-assured displays the level to which someone is more self-confident versus insecure. High scorers tend to be described as worried, self-doubting, guilt prone, insecure and self-blaming. Conversely, low scorers are often seen to be complacent, confident, self-assured and secure.

Tense-Relaxed (Q4). This factor provides a measure of how time driven and patient respondents are. High scorers are commonly driven, tense, impatient, frustrated and full of energy. Low scorers tend to be relaxed, patient, placid, tranquil and composed.

Tough-Mindedness/Receptivity

The global trait of tough-mindedness/receptivity signifies how resolute and tough-minded someone is compared to how intuitive, open-minded, and receptive they are. The scale comprises four primary traits.

Warm-Reserved (A). Please see the description provided above.

Sensitive-Unsentimental (I). The sensitive-unsentimental dimension denotes whether someone is compassionate and sympathetic or objective. High scorers are described as refined, tender-minded, sympathetic, sentimental, and esthetic, whereas low scorers are described as objective, tough, self-reliant, and utilitarian.

Abstracted-Practical (M). Abstracted-practical indicates whether someone is impractical and imaginative or practical and solution oriented. High scorers are frequently considered abstract minded, impractical, and imaginative and low scorers grounded, down-to-earth, conventional, practical, and prosaic.

Open-to-Change/Traditional (Q1). The primary personality factor of open-to-change-traditional depicts how flexible or liberal someone is compared to how conservative they are. High scorers tend to be open to change and experimentation, while low scorers are often traditional and conservative, being attached to familiar ideas and values.

Independence/Accommodation

The broad scale of independence/accommodation measures whether an individual tends to be persuasive, independent and willful, or agreeable, selfless and accommodating. It is represented by four primary traits, including the aforementioned *bold-shy, vigilant-trusting* and *open-to-change/traditional* scales and:

Dominant-Deferential (E). Gauges how co-operative, assertive and dominant participants generally are. High scorers are frequently described as being forceful, assertive, dominant, competitive and stubborn. In comparison, low scorers are considered submissive, humble, obedient, co-operative and deferential.

Self-Control/Lack of Constraint

This scale denotes the degree to which a person is self-controlled and restrained, alongside whether or not they tend to inhibit urges. Please refer to the abovementioned descriptions of *lively-serious* and *abstracted-practical* as they form two of the four factors loading on this global scale. The remaining primary factors loading on this global scale are:

Rule-Conscious/Expedient (G). A primary personality measure that conveys how likely one is to abide by the law and attitudes toward authority figures. High scorers are often described as conforming, moralistic, dutiful, conscientious and rule-bound. Low scorers are considered non-conforming, expedient and self-indulgent.

Perfectionistic-Tolerates Disorder (Q3). A primary scale ascertains the degree to which one is self-disciplined as opposed to impulsive. High scorers are frequently described as being perfectionists, self-disciplined, organized, in control, and compulsive, whereas low scorers are commonly considered flexible, unexacting, undisciplined, impulsive, lax, and uncontrolled.

Reasoning (B)

This primary factor is the only scale within the 16PF that relies on ability or objective based measurement techniques (consisting of correct and incorrect responses). The scale encompasses 15 items that do not load on the five global factors. High scorers on this factor tend to be bright and fast learners, while low scorers tend to display concrete thinking and a lower mental capacity.

Applications in Personality Profiling and Correlates of the 16PF

The most frequent and established application of the 16PF is within industrial and organizational settings, reflecting the strong predictive validity of the scale (i.e. in predicting and understanding important behaviors). Multiple personality profiles for varied professions have been formulated and subsequently utilized to inform employee selection, promotion, and development in the workforce. Please see Cattell and Mead (2008) for an in-depth review.

The scale is also commonly used in research and clinical settings to identify personality correlates with important psychological and social variables, such as self-esteem, happiness, intelligence, masculinity and femininity and attitudes in order to inform treatment, research, and developmental programs (please refer to the further reading list below).

Social Desirability

Amani Elrofaie

Independent Researcher and Policy Analyst

What is Social Desirability?

Researchers across multiple disciplines, most commonly the social sciences, rely on self-report methods to ask direct questions and draw meaningful conclusions. Such methods include rating scales, interviews, and questionnaires, which are used to elicit information about individual behaviors, personality, motivation, beliefs, and so on. Under ideal circumstances, responses garnered through self-report methods emerge from truthful and/or accurate respondent answers, and particularly those which the self-report method aims to test. However, the validity of self-report methods is sometimes difficult to recognize due to response styles, or response bias. They are not often controlled in research. Vaerenbergh and Thomas (2013) define response styles as the tendency for respondents to answer survey questions or rating scales in certain ways, regardless of the content. As a form of response bias, response styles contribute to systematic error through alternative explanations for research results.

Social desirability, which is the focus of this article, is one type of response style in which respondents present themselves in ways that conform to socially acceptable values and expectations; yield social approval; and/or avert criticism. Social desirability was initially conceptualized as a unidimensional construct. In response, instruments were developed to measure individual differences in social desirability, but low correlations between those scales redirected conceptualizations of social desirability to be associated with two factors of awareness: self-deception and other deception. Self-deception occurs when a survey respondent truly believes a statement to be true of themselves, even though it is untrue. Other deception is the case when a respondent misrepresents the truth in order to avoid being evaluated. Alternatively and more recently, Paulhus and John (1998) categorized socially desirable response tendencies as two modes of human experience: agency and communion. According to the researchers, some respondents would be more likely to provide socially desirable responses in agency-related contexts. Those fall under conditions where respondents are asked questions that elicit egoistic response tendencies (ERT),

which involve such aspects as independence, assertiveness, dominance, uniqueness, mastery, and influence. Other respondents, on the other hand, are more likely to provide socially desirable responses in communion-related contexts, which involve love, intimacy, belonging, connectedness, approval, and nurturing behavior. Paulus and John referred to these types of socially desirable response domains as moralistic response tendencies (MRT). With regard to individual differences in socially desirable responses, gender is a socio-demographic variable that has been repeatedly examined in the context of ERT and MRT. Differences may be explained by traditional, gender-based socialization roles, wherein men consistently score higher on ERT than women. Research has also consistently shown that women score higher on MRT than men. This is according to research by Lawlani, Shavitt, and Johnson in 2006.

The concept of social desirability first came to prominence through the works of Allen L. Edwards (1953, 1957), under the context of personality characteristics and assessment. Academics like Jackson and Messicks (1958) explored social desirability as a type of response style. Both contexts contribute to a strong working definition of social desirability, which is worthy of study due to its relevance in survey design, market research, personality research, and in the social sciences in general, and especially due to its status as one of the most common sources of bias affecting the validity of experimental and survey research findings. Respondents of self-reports are commonly swayed by social desirability in questions that address socially sensitive or personally private issues. When faced with such issues, respondents might provide responses that are either exaggerated or inflated, underplayed or deflated, or completely denied. A study on physical activity levels by Adams et al. (2005), for example, found that participants with high social desirability scores were significantly more likely to overestimate their physical activity levels. Self-report themes in which social desirability is a concern include:

- health and physical behaviors (e.g. dietary intake, exercise, sexual practices, compliance with medicine dose prescription);
- personal habits (e.g. work ethic, spending habits);
- personality/temperament (e.g. honesty, humor, aggressiveness);
- social activities (e.g. religious beliefs, charitable actions, patriotism); and
- societal taboos (e.g. participation in illegal activities, domestic violence).

Studies have demonstrated that social desirability can bias laboratory- and survey-based research. One classic study by Nederhof (1985) reported that 10–75% of the variance in responses can be explained by social desirability, which can confound relationships among variables of research interest. In many instances, social desirability obscures or suppresses relationships among variables in ways that produce artificial relationships among or between variables. On the other hand, the impacts of social desirability can sometimes be minor. A study by Klassen and colleagues (1976) identified an effect that was pervasive, but lacking social desirability, with the highest correlation making up only 10% of the variance. The differences in results are expected when considering the significance of environmental influences and sample type on social desirability, as well as the self-report themes of focus. However, meta-analyses suggest that social desirability is the same between paper and online self-report methods, as well as those administered in person.

Ways to Overcome Social Desirability

Detection and Measurement

Researchers in the fields of psychology and sociology have developed and validated a variety of control methods to detect and measure data that is systematically biased by socially accepted responses. Most notably, the 33-item Crowne-Marlowe Scale (CMS; Crowne and Marlowe, 1964) measures individual differences in the tendency to give socially desirable responses. Conveniently, respondents are given the CMS questionnaire, along with the questionnaire of focus. They are asked to answer true or false questions to a set of socially desirable, but improbable statements, like "Before voting, I thoroughly investigate the qualifications of all candidates." Items in the questionnaire of focus that are strongly influenced by social desirability will correlate substantially with the respondent's scores on the CMS. However, items not strongly affected by social desirability will correlate minutely with the CMS. The CMS has been translated into several languages (e.g. Hermans, 1967). It has also undergone a multitude of examinations by other academics, including Millham (1974) and Ramanaiah and Martin (1980), to test its validity and to critique its methodological flaws (e.g. Edwards, 1970; Millham and Jacobson, 1978). Another commonly used index for detecting social desirable responses is the Balanced Inventory of Desirable Responding (BIDR; Paulhus, 1998), which is viewed by some researchers as more sensitive than the CMS due to its incorporation of newer theoretical and empirical understandings of social desirability and more sophistical multivariate techniques. It measures a respondent's tendency to give socially desirable responses on self-report inventories, consisting of 40 items on 7-point scales (1 = Not true to 7 = Totally agree) or 5-point scales (1 = Not true to 5 = Very true). The BIDR measures respondent tendency to unconsciously give unrealistically favorable self-descriptions and consciously dissimulate or "fake good." Consistent with previous research, a study by Lambert et al. (2016) showed that both the CMS and the BIDR have substantial ability to detect social desirability in self-reports.

Reliable short form versions of the CMS have also been developed by such researchers as Loo and Thorpe (2010), Fischer and Fick (1993), Ballard (1992), Zook and Sipps (1985), Silverstein (1983), Reynolds (1982), Nederhof (1981), and Strahan and Gerbasi (1972). The use of such scales provides three ways of coping with social desirability, including the questionable, yet sometimes used method of rejecting of high-scoring data. As well, users of social desirability scales can correct data of high social desirability scorers by adjusting them according to control group or neutral task data, or by merely registering the impact of social desirability as a study limitation.

Prevention and Reduction

Researchers utilize general principles to prevent and reduce socially desirable responses when developing test items. Such methods are useful for making sure that an item assesses only the trait that it is designed to measure and are approached through management of the situations in which data collection takes place. Naturally, creativity and reliability of all solutions are subjected to critique. For example, items can be written such that responses fall under competing social desirability. This is the case in forced-choice items as a method

of coping with social desirability (Edwards, 1957, 1970). Respondents are made to choose between two items that possess an equal amount of social desirability with the rationale that if both items seem equally desirable, the respondent choice is not influenced by social desirability. An example presented in the Preference Record of Kuder (1939) is, "Take a photograph of a table you would like to make" or "Take a photograph of a champion swimmer."

Alternatively, items on personality questions can be devoid of highly socially desirable features. Indirect or neutral questioning techniques elicit answers from the perspective of another person or group, rather than the respondent's own perspective. They are useful for framing embarrassing questions or those that may project an unfavorable image of the respondent. Fisher (1993) has reported that indirect questioning reduces social desirability bias and has no additional systematic effects on mean scores. This method is pervasive in marketing and consumer behavior research.

Use of self-administered questionnaires isolates the respondent as a way of potentially reducing the salience of social cues. In other words, this method ensures respondent anonymity through the absence of an interviewer. While some studies have found that anonymous mail and online surveys yield data that is less influenced by social desirability than telephone or face-to-face interviews, other studies contest that there are no differences in distortion of answers between varying methods of administration.

Overall, combining methods for detecting, measuring, preventing, and reducing social desirability can contribute to experimental and survey research data that is valid. Social desirability represents only one type of response that is overcome through combinations of measurement instruments and research practices that are used for detection and prevention in research and clinical contexts. Their use will certainly continue to be enhanced in the future.

Social Intelligence

Richard E. Boyatzis

Case Western Reserve University

The term "social intelligence" (SI) was first noted by Thorndike (1920) as a meaningful component of a person's intelligence. But the appreciation of the need for interpersonal ability dates far back from the era of modern psychology. Aristotle (352 BCE) noted, "Man is by nature a social animal; an individual who is unsocial naturally and not accidentally is either beneath our notice or more than human. Society is something that precedes the individual. Anyone who either cannot lead the common life or is so self-sufficient as not to need to, and therefore does not partake of society, is either a beast or a god." On the other side of the world, a little earlier, Confucius discussed the importance of building and honoring relationships to others. In *The Analects,* he said that the basic concept of benevolence, which he called ren, was that a person "wishing to be established himself, seeks also to establish others; wishing to be enlarged himself, he seeks also to enlarge others" (Confucius, 1979, originally fifth century BCE). In more recent periods, a person's ability to build and maintain relationships, to work, live and love with others has evolved. Gardner (1983) considered interpersonal intelligence one of the seven forms of intelligence a person has.

While definitions will vary, SI is a set of abilities that enable a person to build and maintain healthy relationships, whether in dyads, teams, or large groups. Most simply, it is the ability to live, love, and work with others. In terms of behavior, Boyatzis (2009) defined "a social intelligence competency is the ability to recognize, understand and use emotional information about others that leads to or causes effective or superior performance." For a comprehensive review of SI, see Cantor and Kihlstrom (1987) and Goleman (2006).

SI has been shown to predict effective leadership, management, and professional performance (Boyatzis, 2009; Cantor & Kihlstrom, 1987). It has also been shown to predict loving and stable marriages (Gottman, Murray, Swanson, Tyson, & Swanson, 2002) and relationships in general. Life satisfaction is more likely a function of one's social networks and relationships, and even physical health throughout the age spectrum is linked to the quality of one's active relationships (Putnam, 2000). The quality of one's social relationships

and interactions has even been claimed to delay onset of cognitive decay resulting from neuro-degenerative disorders (Petersen et al., 2015).

Multiple Levels of Social Intelligence

Recognizing that our social abilities take on many forms helps avoid the trap of arguing one variable as the essential component and appreciating that SI exists at multiple levels within a person (McClelland, 1951; Boyatzis, 1982 cf. in Boyatzis, 2009). There are neural networks that enable a person to "see" and notice others, to attend to them, and others that inhibit that ability. These operate unconsciously and quite fast (33 ms to recognize a face). Then moving slightly closer to consciousness, we have personality traits, like agreeableness or empathic concern, and motives, like the needs for affiliation and power, also unconscious. Still rising closer to consciousness are the levels of values and attitudes, which McClelland called the self-schema (1951). Somewhere between consciousness and just below the level of consciousness, exists the knowledge about SI (Cantor & Kihlstrom, 1987). Moving into full consciousness is the behavioral level, that which can be seen by others, which can include skills, like listening, or competencies, like influence (Boyatzis, 2009; McClelland, 1973). All of these components integrate into a person's SI. It is assumed that SI at one level will affect the existence and activation of SI at another level. Some research has explored these interactions, but the research documentation is sparse because of the epistemological silos in which many scholars work.

When used appropriately, measures of SI or its components should reflect the specific level of SI being studied. For example, the assessment of the default mode network activation requires an fMRI or similar method. Assessment of a performance trait such as empathy would require a measure like the Profile of Nonverbal Sensitivity (PONS; Rosenthal, Hall, DiMatteo, Rogers, & Archer, 1979). The motive level is assessed through a Thematic Apperception Test (TAT), and for more value based definitions of motives, there may be self-report surveys to assess it. The behavioral level of SI, called SI competencies, is assessed best through informants' observations from multi-source analysis like a 360 assessment, or coding of audio or video tapes of critical incidents or simulations (Boyatzis, 2009).

Neural Networks and Too Little or Too Much SI

Although many parts of the brain are involved in social interaction, one major network, the default mode network (DMN), is particularly important for SI. This is the network that enables a person to notice and focus on others, as well as emotions and moral concerns, and new ideas. Kahneman (2011) called this the fast system in his dual process theory. The challenge is that tasks involving analysis, numbers, and abstractions, like decision-making and problem-solving, activate another dominant network called the task positive network (TPN). While both are important at work and in life, they suppress each other (Jack et al., 2013). Spending a great deal of time in work environments that focus on budgets and analysis will make it more difficult for a person to develop or use SI (Boyatzis, Rochford, & Jack, 2014).

Too little demonstrated SI will emerge as dysfunctions that include autism, which is, to simplify it, a difficulty accessing the DMN among other things. Abrasive personality syndrome is often a result of poor SI. This is often seen as the major contributor to why 70% of people in full-time work in the United States do not feel engaged in their work. Although emotional intelligence has received a great deal of attention, it is the relative lack of SI that is the likely culprit in poor performance at work and in family disruptions.

Can SI Be Developed?

The answer to the age-old question as to nature or nurture, SI can be developed. This does not mean that some aspects are not present at birth, for example agreeableness seems to have some genetic basis. Longitudinal research has documented the development of the behavioral level of the SI competencies (Cherniss & Adler, 2000; Boyatzis, Stubbs, & Taylor, 2002) in adults. Development of SI in children has also been documented in multiple studies using an approach called "socio-emotional learning" (Durlak, Weissberg, Dymnicki, Taylor & Schellinger, 2011).

Temperament, Personality Correlates of

Paul F. Tremblay

University of Western Ontario

Temperament Conceptualized

Temperament is the totality of the biologically based psychological individual differences that are expressed and detectable early in life. The fact that these differences can be observed in newborn infants, at an early stage when the social environment could not have played a substantive role, suggests important genetic and prenatal environment influences. With time, the variation in behavior of infants continues to be heavily influenced by biological factors, and cross-situational consistency and temporal stability increase. By the age of 3, temperamental traits show some stability but these are basic and simple psychological systems (e.g. emotional reactivity, activity level, and affiliation) that have not yet developed into more complex cognitive systems seen later in childhood. With development of motivational, attention, and cognitive systems come individual differences in self-regulation abilities. Further development also leads to more advanced self-regulation systems based on capabilities to imagine future goals.

A trait can be said to represent a continuum with bipolar opposites. Taking the example of the trait extraversion, we can describe the bipolar opposites as extraverted and introverted. Cross situational consistency and temporal stability (at least over medium-term periods of a few years) are the basic features of personality or temperament traits that make it possible to identify and differentiate individuals from each other and to be able to say, "I know this person." Thus a person who is described as extraverted will have a tendency to be extraverted consistently across various situations (e.g. at work, in intimate relationships, and in daily interactions with people) and will tend to maintain that pattern of behavior over a period of years or even decades.

Research on Temperament

Some Early Beginnings in Temperament Typology

Of particular interest to the modern study of temperament is the contrast between personality traits and personality types. In general, personality types refer to categorical distinctions used to classify objects, animals, or people. One early typology of temperament consists of the fourfold classification of the bodily humors consisting of blood, phlegm, black bile, and yellow bile proposed by the second-century Greek physician Galen. A specific temperament was associated according to which of these fluids were in higher concentration in the body as follows: sanguine (warm), phlegmatic (apathetic), melancholic (sad) and choleric (easily angered). Another typology initially proposed by Ernst Kretschmer in 1925 and developed further by William Sheldon in the 1940s linked specific body types to temperament patterns. These body types – endomorphic (soft, rounded), mesomorphic (hard, rectangular, muscular), and ectomorphic (thin, fragile) – were linked to temperaments of easy going, dominant/aggressive, and introverted/private respectively. Essentially no empirical evidence has supported these early typologies. Modern research on temperament focuses more heavily on trait models of variation, hypothesizing that for most traits, individuals vary along a continuum showing a nearly normal distribution.

Criteria for Thinking About Temperament

Buss and Plomin (1984) proposed five criteria to provide evidence that a trait falls within the domain of temperament: the trait is (1) inherited, (2) relatively stable during childhood, (3) retained into adulthood, (4) evolutionarily adaptive, and (5) present in our phylogenetic relatives. Research over the years has indeed produced evidence satisfying these criteria within the areas of behavioral and molecular genetics, child development psychology, child to adulthood longitudinal research, evolutionary psychology, and temperament studies in non-human animals. In addition to these five criteria, psychobiological models of temperament have also been developed, and cross-cultural research has supported the universality of specific temperamental traits across cultures.

Behavioral Genetics and Molecular Genetics

Temperament is influenced by genes, environment, experience, and maturation. The study of behavioral genetics has demonstrated through various twin research paradigms that heredity plays a significant role in temperament. Another important finding is that of a gene–environment correlation, whereby genetic and environmental influences on temperament and behavior are not independent. For example, a child's initial temperament can influence the responses he or she evokes from parents. The parents' responses in turn influence the child's later temperament and related behaviors. Environments are also selected based on temperament. A child who is introverted will be likely to seek quiet environments.

Molecular genetic studies have investigated the influence of specific genes on specific psychological outcomes related to temperament such as aggression and depression. Some studies have also found evidence of trait by environment interactions. In some cases, these

interactions suggest that the influence of the gene manifests itself only under specific environmental influences. For example, in one seminal study Caspi et al. (2003) found that the exposure to stressful life events influenced the likelihood of developing depressive symptoms, but only among individuals with one or two copies of the 5-HTTLPR short allele. These interaction effects are small and are difficult to detect with small sample studies.

Temperament in Early Life

Alexander Thomas and Stella Chess, two psychiatrists, conducted pioneering work on temperament in infancy, beginning in the 1956 New York Longitudinal Study (Thomas & Chess, 1977). They studied individual differences in primary reaction patterns in infants (beginning at 3 to 6 months of age) by interviewing parents about their infants' behavior in varying contexts. Their observations and assessments were summarized along nine dimensions of temperament: regularity or rhythmicity of behavior, adaptability to changes in the environment, approach and withdrawal in responses to novelty, threshold of responsiveness (i.e. amount of stimulation necessary to produce a reaction), intensity of reaction, quality of mood based on the amount of positive and negative feelings, distractibility based on the effectiveness of external stimuli to capture the child's attention, and attention span and task persistence. Mary K. Rothbart, an influential researcher in child temperament, has suggested that the structure of temperament in childhood consists of three broad dimensions: Negative Affect, Surgency, and Effortful Control. The more basic domain of reactivity underlies the dimension of negative affect and surgency, while effortful control refers to a major process of self-regulation.

Long-Term Longitudinal Research

Consistency and stability in temperament from infancy to adulthood, and the structure of temperamental traits present early in life, converge with the structure of personality traits in adulthood. Individual differences in childhood temperament have been shown to predict, to some extent, adult outcomes including adult personality traits, psychopathology, and school achievement. A number of studies have investigated the stability of temperament from childhood to adulthood and found some evidence of stability. For example, in a longitudinal study of 1,000 children born in Dunedin, New Zealand, Caspi et al. (2003) assessed their temperament at age 3 and personality traits at age 26. These longitudinal studies have revealed that impulsivity in childhood predicts problems in adolescence and adulthood (e.g. suicide risk, hostility, crime, substance dependence, psychopathy, narcissism, and executive functions). Also, high reactivity and irritability at 4 months, shyness at 20 months, and inhibition at 3 years predicted anxiety, shyness, and depression in adolescence and adulthood. Other longitudinal studies have found similar patterns. Taken collectively, the long-term studies indicate that two traits appearing in infancy and toddlerhood, impulsivity/inattention and behavioral inhibition, are predictive of outcomes in adolescence and adulthood. At the same time, it is important to note that temporal stability does not mean that people do not change but that they maintain a similar rank order position across time. For example, the child in kindergarten that was ranked the highest in extraversion would be somewhat likely to rank among the highest at a class reunion 20 years later.

Evolutionary Psychology

Temperament dimensions of affect, action, and attention may be seen as adaptive mechanisms designed throughout our evolutionary history. A number of reasons have been suggested for why genotypic and phenotypic variation exists in these dimensions and manifest themselves as individual differences in temperament (Ashton, 2013). One idea is that both ends of any of the basic temperamental dimensions, such as extraversion and introversion, were selected because the net benefits of one pole did not consistently outweigh those of the opposite pole. The overall advantage of having higher or lower levels of a trait would have depended on various environmental circumstances. Another proposed idea known as frequency dependence suggests that there might be an ideal balance of people with different levels of a temperament dimension.

Temperament in Non-human Animals

If temperament is biologically based, then temperament traits should also exist in non-human animals. Numerous studies have found evidence of this hypothesis in species such as chimpanzees, cats, dogs, donkeys, hyenas, and octopuses. In their review of animal studies that included 12 non-human species, Gosling and John (1999) found evidence that individual difference variation in behavior could be organized along dimensions that resembled the human five factor model dimensions of extraversion, neuroticism, and agreeableness. There was some evidence of openness to experience but mostly with respect to curiosity and not to more advanced activities including use of symbols. Evidence of conscientiousness was limited to chimpanzees who showed some primitive forms of organization and planning. These similarities across a wide range of animal species provide evidence of underlying biological mechanisms.

Psychobiological Models of Temperament

Hans Eysenck and later Jeffrey Gray posited neurobiological models for temperament. Eysenck proposed that the dimension of extraversion was associated with variability in cortical arousal, and that the dimension of neuroticism was associated with individual differences in the limbic system. Gray proposed a behavioral activation system (or BAS) and a behavioral inhibition system (or BIS) as the basic dimensions of temperament. These are broad systems that incorporate more specific traits. For example, dispositions in sensation seeking, impulsivity, and aggression fall within the domain of the activation system, whose function in evolutionary history has been to motivate approach behaviors toward sources of rewards. This system is associated with brain dopaminergic reward-seeking mechanisms. The BIS has an opposite role of avoiding and withdrawing from threats in the environment and involves fear and anxiety responses.

Future Research Directions

Research in temperament will continue in all directions described above, bridging gaps and advancing knowledge in the relations between genetic, brain, and psychological elements.

Technological advances will lead to more precise and feasible measurement at the genetic and neurophysiological level, and will also lead to larger information processing algorithms for modeling evolutionary mechanisms and gene-by-environment processes. The fact that temperament traits associated with risks of later problem behaviors can be assessed as early as the second year of life provides valuable directions for prevention of social and health-related problems such as addiction and crime. In fact, although most prevention work occurs with children of school age, more and more assessments will be conducted in pre-school especially for the early detection of externalizing behaviors. Another research direction involves the relation between temperament and pharmacotherapy. Initial research has revealed that people may respond differentially to drug treatments such as antidepressants due to differences in the neuroaffective bases of their personalities. Overall it will be important to bridge temperament research in biological psychiatry, psychopharmacology, clinical psychology, and developmental psychopathology.

Test Anxiety

Moshe Zeidner

University of Haifa

Societal and Cultural Context

The long-standing academic and public interest in test anxiety is largely due to the increasing personal salience of evaluative situations for people in modern society (Zeidner, 1998). Myriad forms of tests, evaluation procedures, and assessments are now used widely by education practitioners, clinicians and the industrial, government, and military sectors to diagnose, assess, and help make decisions about people. Many persons have the ability to do well on exams but perform poorly on cognitive tests due to debilitating levels of test anxiety. Consequently, test anxiety may limit educational and vocational development because test scores influence entrance to many educational or vocational training programs in modern society.

Testing of school-age children and youth in the United States has continued to increase over the past few years. This trend is primarily due to an emphasis on the accountability of schools to increase their students' achievements following the *No Child Left Behind* legislation of 2001. This has resulted in increased pressure on school students to succeed, and potentially increasing levels of stress and evaluative anxiety in student populations.

Recent examinations of the prevalence for test anxiety in Western society suggest estimates close to 25–40% of the population. In addition, test anxiety is a near-universal phenomenon, experienced by people in different cultures across the globe. Meta-analytic data from various national sites show that although mean test anxiety levels vary somewhat across cultures, test anxiety is a prevalent and relatively homogenous cross-cultural phenomenon. Whereas women report higher levels of test anxiety than men, the gender difference generally does not translate into objective performance differences.

Definition and Conceptualization

Test anxiety refers to the set of phenomenological, physiological, and behavioral responses that accompany concern about possible negative consequences or failure on an exam or similar evaluative situation (Zeidner, 1998). Test anxious students have been reported to manifest a host of deficits in information processing during encoding, processing, and retrieval of information. Also, during assessment sessions, test anxious students are reported to suffer from heightened emotional arousal, and worry excessively about exam failure. In addition, many test anxious students are also reported to experience deficits in study skills and test taking, with poor preparation a major catalyst for anxiety in evaluative situations (Zeidner, 1998).

Researchers have found it useful to differentiate between three related facets of test anxiety: a *cognitive* facet (worry, irrelevant thinking, etc.), an *affective* facet (tension, perceived arousal), and a *behavioral* facet (deficient study skills, procrastination, avoidance behaviors, etc.). In any given test situation, test anxious subjects may experience all, some, or none of these test anxiety reactions. The specific anxiety response manifested may vary, depending on the constitutional qualities and past experience of the individual, the nature of the problem to be solved, and various situational factors affecting the level of anxiety evoked.

The test anxiety construct was dramatically advanced by a number of important conceptual distinctions, which helped refine thinking and research in the area. Alpert and Haber differentiated *facilitating* and *debilitating* anxiety, with facilitating and debilitating anxiety, respectively, claimed to lead to task-related and task-irrelevant behaviors during test situations. Yet another conceptual contribution, advanced by Liebert and Morris, was the critical differentiation between *worry* and *emotionality* components of test anxiety. According to this conceptualization, anxiety was viewed to be a bi-dimensional phenomenon, including cognitive (Worry) and affective (Emotionality) components. These two components are revealed to be empirically distinct, though correlated, and worry relates more strongly to test performance than does emotionality. This distinction proved to be instrumental in shifting test anxiety research toward a more cognitive orientation.

Although the question still looms large whether test anxiety is best conceptualized as a relatively stable personality trait (individual difference variable) or an ephemeral emotional state, a widely accepted conceptualization proposed by Charles Spielberger (1995) proposed a hybrid term by construing test anxiety as a *situation-specific personality trait*. Accordingly, test anxiety refers to the individual's disposition to react with extensive worry, intrusive thoughts, mental disorganization, tension, and physiological arousal when exposed to evaluative situations.

Past and Current Conceptions

Throughout its relatively brief history as a scientific construct, test anxiety has taken on a variety of different meanings as a function of both changes in the "Zeitgeist" coupled with variations in the theoretical persuasions of the individual investigators involved in this research arena. Thus, in the early days of test anxiety research, the construct was initially defined in *motivational* terms, either as drive level, goal interruption, or need to avoid failure. With increasing interest in personality research, test anxiety was conceptualized as

a relatively stable *personality disposition* that develops when parents hold exaggerated expectations and are overcritical of their children's achievement efforts. In keeping with the cognitive revolution of the late 1960s and early 1970s, test anxiety came to be viewed primarily as a *cognitive-attentional* phenomenon. Accordingly, the highly anxious person is one who attends, in an exaggerated way, to evaluative cues, to self-generated concern about ability to do well enough, and to feelings of physiological arousal.

More recently, Zeidner and Matthews (2005) have emphasized the distinction between test anxiety as an attribute of the person, and as a dynamic process. From the first perspective, dispositional test anxiety may be construed as a *contextualized personality trait*, referring to the individual's disposition to react with extensive worry, intrusive thoughts, mental disorganization, tension, and physiological arousal when exposed to evaluative contexts or situations. The more transient state expressions of anxiety may be assessed separately from the more stable trait. From the second, process-oriented perspective, test anxiety depends on the reciprocal interaction of a number of distinct elements at play in the ongoing stressful encounter between a person and an evaluative situation. These elements include the evaluative context, individual differences in vulnerability (trait anxiety), threat perceptions, appraisals, and reappraisals, state anxiety, coping patterns, and adaptive outcomes.

Assessments

Self-reports include any direct subjective report by the person regarding his or her own test anxiety responses, usually elicited via questionnaires or single-item rating scales. Self-report inventories have been the most prevalent format for assessing test anxiety, largely because they are considered to provide the most direct access to a person's subjective experiential states in evaluative situations, possess good psychometric properties, are relatively inexpensive to produce, and are simple to administer, score, and interpret.

Among the most widespread contemporary measures of test anxiety are Spielberger's Test Anxiety Inventory, Sarason's Reactions to Tests, Suinn's Test Anxiety Behavior Scale and Benson et al.'s Revised Test Anxiety Scale. Most popular test anxiety inventories have satisfactory reliability coefficients, typically in the high .80s to low .90s. During longer intervals between assessments, personality traits, such as test anxiety, may change, causing lower stability coefficients. Scores on ability tests, grade point average, observer ratings, behavior in structured evaluative situations, and the like have been employed as measures of criterion behaviors.

A variety of less frequently used assessments have been employed to assess anxiety, including "think-aloud" procedures (e.g. "Please list as many thoughts and feelings as you can recall having during this test"), physiological measures designed to gauge changes in somatic activity believed to accompany test anxiety (e.g. pulse, heart rate, respiration rate, skin resistance level), trace measures (e.g. accretion levels of corticosteroids, adrenaline products, urea glucose), performance measures (e.g. examination scores, semester grade point averages, latency and errors in recall of stress-relevant stimulus materials), and unobtrusive observations of specific behaviors reflective of test anxiety in a test situation (perspiration, excessive body movement, chewing on nails or pencil, hand wringing, "fidgety" trunk movements, and inappropriate laughter when subjects were engaged in exam situations).

Anxiety assessments need to be understood within the context of a student's life and social and cultural milieu. Thus, understanding the results of a score on an anxiety measure requires appreciation of the possible multiple and interactional influences on anxiety. This includes the subject's past affective and academic history, and current social, emotional, vocational, and economic adjustments, as well as behavior during the exam.

Anxiety and Cognitive Performance

Hundreds of studies have probed the pattern of relationships between anxiety and a wide array of cognitive performances. A meta-analytic review by Hembree (1988), based on 562 North American studies, demonstrated that evaluative anxiety correlated negatively, though modestly, with a wide array of conventional measures of school achievement and ability at both high-school and college levels. On average, the mean effect of test anxiety on depressing student test scores was about a fifth of a standard deviation. Other integrative reviews by Seipp and Ackerman revealed similar effects.

The information-processing components found to be sensitive to anxiety in lab experiments relate to encoding, information storing and processing, and information retrieval and production. These anxiety-related deficits at various stages of processing suggest some general impairment in attention and/or working memory.

Interventions

Test anxiety treatment fashions and orientations mirror the evolution of the behavior therapies, having swayed sharply from the psychodynamic to the behavioral, and more recently to the cognitive perspective. Most intervention methods are embedded in a multidimensional context. At present, a combination of procedures (whether combined in a truly integrative manner or in the stance of technical eclecticism) seems to best represent the true nature of the test anxiety intervention process.

Current attempts have typically focused on treatments directed toward the emotional, cognitive, or behavioral facets of anxiety. Thus, treatment programs typically include *emotion-focused* treatments, designed largely to alleviate negative emotional affect experienced by anxious students, *cognitive-focused*, treatments designed to help the anxious client cope with worry and task-irrelevant thinking, and *skills training*, designed to improve various skills among students (social, athletic, motor, study, test-taking skills) and enhance their performance. A number of meta-analyses have pointed to the effectiveness of the treatment of anxiety among school children, with mean effect sizes estimated around two-thirds of a standard deviation unit.

Directions for Future Research

Although anxiety research over the past 65 years or so has made important strides in mapping out the anxiety terrain, there is still much uncharted territory that needs to be explored and more extensively mapped out by future research (see Zeidner, 2014). This includes:

- Development of a comprehensive taxonomy of anxious students;
- Research addressing different grain sizes and levels of discourse with respect to anxiety in students (biological, programming, and knowledge levels);
- Pinpointing neural mechanisms accounting for the anxiety phenomenon and its key manifestations;
- Large-scale and systematic research relating to various facets of anxiety, based on multiple observations of various student target groups, at various time points, and in various educational and social contexts and cultural settings;
- Empirical research in natural evaluative settings;
- Detailing how anxiety influences the more complex processing competencies that are often important in real-life settings (decision making, inductive and deductive processes, creative behavior).

Trauma

Aleksandar Dimitrijević and Andreas Hamburger

International Psychoanalytic University, Berlin

Trauma is a result of an internal or external event that stimulates the mind to an unbearable degree. It can be a result of natural disasters, individual violence, and/or socially organized perpetration, which may have grave consequences for somatic and mental health. It is also socially relevant, because long-lasting post-traumatic disorders put a serious burden on the health system. From a sociological perspective, specific social traumatic experiences, if culturally acknowledged, sometimes serve as a key narrative for social identity.

It is important to emphasize that not every trauma exposure leads to a post-traumatic symptomatology. An overall rate of post-traumatic stress disorder (PTSD) was found to be 15.9% in children and adolescents following trauma exposure, varying from 8.4% in boys exposed to non-interpersonal trauma to 32.9% in girls exposed to interpersonal trauma (Alisic et al., 2014).

Trauma was a very important topic of nineteenth-century French and German medicine. It came to prominence with Sigmund Freud and was much studied by psychoanalysts. Kaplan's widely used "Synopsis of Psychiatry" has up to the 1980 edition relied on a 1955 study that had claimed incest occurred in just one out of 1 million American families (after Ross, 1996, pp. 6–7). More recent estimates claim that there are approximately 1 million cases of child abuse and neglect substantiated in the United States each year (U.S. Department of Health, 2012, www.acf.hhs.gov).

Types of Trauma

More recent surveys claim that there are 676,569 cases of child abuse and neglect substantiated in the United States each year, which is 9.1 victims per 1,000 children in the population (U.S. Department of Health and Human Services, 2012): (1) Symptoms following non-intentional trauma decrease within three months, while those following intentional trauma increase steadily; (2) risk of PTSD varied from 53.8% after being held captive or kidnapped, to .2% after having detected a dead body; (3) battle groups were more severely

affected by PTSD than subjects who experienced civilian terrorism or work and traffic accidents; (4) a study using structured clinical interviews with 157 help-seeking children aged 8–17 found that confrontation with traumatic news, witnessing domestic violence, physical abuse, and sexual abuse were significantly associated with PTSD, while witnessing a crime, being the victim of a crime, and exposure to accidents, fire or disaster were not; (5) childhood abuse, but not neglect, predicted later positive psychotic symptoms, even when victims were compared to siblings; (6) difficulties in emotional regulation associated with PTSD in trauma survivors were significantly higher in those with early-onset chronic interpersonal trauma than in those with single-event and/or late-onset traumas.

Adverse Childhood Experiences

A study of adverse childhood experiences that included more than 17,000 adults revealed that the incidence rate for different types of trauma is alarmingly high (for a review see Dimitrijevic, 2015). In some cases, one-quarter or even a third of the subjects were exposed to trauma during childhood, with strong gender differences (e.g. there are more physically abused men, but more sexually abused women). More than one-third of the sample had grown up without serious trauma. However, 63.9% subjects had been traumatized at least once and, worse still, as many as 37.9% were traumatized more than once, and every eighth subject experienced adverse experiences repeatedly (four or more times).

Most maltreatment happens in very early childhood, when it has greater negative effects on developing minds and brains. A troubling 5.7% children of ages 0–3 experience trauma or neglect, which is followed by a steady decline, to reach 1.9% at the age 16–17 (see Dimitrijevic, 2015).

Incidence of family trauma is also disturbingly high, and especially for women. Every fifth subject has experienced at least one type of household dysfunction, and some more than one.

Social Trauma

Man-made traumatizations touching great parts of the population, like those caused by genocide, war, dictatorship with racist, ethnic, and political persecution, have a special position among all possible sources of trauma. Social trauma includes (1) organized, intentional perpetration by one social group (for example, nation) against (2) not an individual, but another social group.

While we may hope that a traumatized individual, even a child, can find some support and comfort, social trauma destroys societal and cultural foundations whose support and comfort we otherwise take for granted: home, language, joint memories, as well as hospitals, counseling and psychotherapy services, legal system, etc.

Not only is social trauma important for individuals and groups who need help (see below), but in the core of large group identity. Psychoanalyst and renowned international peace negotiator, Vamik Volkan (1997, 1999) initiated a concept of "chosen trauma," which is widely used. Volkan's comparative research showed that one event – a death, massacre, or genocide a lost battle or kingdom – often becomes a centerpiece of national identity. It is then difficult to negotiate or compromise, because people have an impression that they are betraying this painful myth.

Consequences of Trauma

Many clinical psychologists have, in studies of various types, found that consequences of childhood trauma include but are not limited to the following (see Dimitrijevic, 2015):

- more frequent adoptions, child fatalities, developmental delays;
- poor attachment and socialization, low self-esteem;
- distortions in sensory perception and meaning, constrictions in action, deficits in readiness to learn, attention, abstract reasoning and executive function;
- hormonal dysregulation, smaller frontal lobe volume, asymmetry of left and right brain centers included in the cognitive processes of language production.

Besides developmental and health issues, trauma is especially important for the field of mental health care. The more traumatic events experienced during childhood, the more likely the person is to develop mood disorder, anxiety disorder, substance abuse or impulse control disorder (see Dimitrijevic, 2015). Furthermore, early individual traumata are 4–10 times more frequent among psychiatric patients than in general populations. This is further underlined by comparison studies that established differences between psychotic patients with a history of childhood trauma and those without it (see Dimitrijevic, 2015), which resulted in the finding that the consequences of childhood trauma are associated with:

- more self-mutilation, higher symptom severity, more suicide attempts;
- earlier first admissions;
- more medication;
- longer and more frequent hospitalizations and seclusions.

It was also shown that social trauma has profound negative consequences. A study with 12,746 participants, which compared Holocaust survivors with control groups with no Holocaust background (see Hamburger, 2017) demonstrated that Holocaust survivors were less well adjusted, particularly showing substantially more PTSD symptoms. Another finding was that they also showed remarkable resilience. Higher rates of mood and anxiety disorders were associated with having more potentially traumatic experiences during and after the war in a study that employed multivariable analyses across former Yugoslav republics where 3,313 subjects were interviewed (see Hamburger, 2017).

Connection between family and social trauma was confirmed in a study that showed significant differences in attachment styles related to types of war exposure in three samples of adolescents who grew up under different war impact conditions in towns of three former Yugoslav republics (see Hamburger, 2017).

Testimonial interviews with Holocaust survivors, slave laborers, and survivors of the genocide in Rwanda (for a detailed review see Hamburger, 2017) demonstrated typical cognitive and emotional symptoms: survivors do not have a life history in the form of a coherent autobiographical narrative, and they display "an erasure" of feelings, comprising a massive denial and/or disavowal of trauma, extreme ambiguity, speechlessness, psychotic or seemingly psychotic delusions and other psychotic and psychosomatic symptoms, frequent nightmares, flashback memories, as well as daydreams of persecution.

How Does Trauma Work?

Traumatized children, especially if by intentional traumatization within the family, move toward parents and at the same time away from them and are forced to create multiple models of caregivers. Faced with the situation in which, for instance, the father, the supposed or until recently the actual source of comfort and love, starts abusing him or her, the child may unconsciously decide to sacrifice his or her own mind in order to save the representation of the father. These children may split their memory, cognition, and emotions in order to separate two types of experiences with the parent: loving father from abusive father. There is, then, one part of themselves they do not dare admit even to themselves, one part too horrible to face. The traumatized child first defensively inhibits their capacity to think about inner states of others and her/himself, trying to avoid the insight that the parent may wish to hurt them. Consequently, trauma impedes deeper procession of emotional experiences and interferes with the (further) development of mentalizing capacity or can even destroy it.

This experience may generalize and the child then feels that "looking inside" is dangerous under any circumstances. Being unaware of inner psychological processes means, of course, that you cannot control or regulate them. This is considered to lead not only to disorganized attachment, but to some forms of mental disorders as well.

The involvement of the social environment in the traumatization of a whole group causes severe trauma consequences visible on an interactional level. Denial of acknowledgment, a conspiracy of silence, institutional rejection, breakdown of a successful myth construction, and, moreover, of historical elucidation are among the social symptoms perpetuating social trauma. This also has consequences for the traumatized individual, who, in a scarred and sometimes hostile environment, is then deprived of major resilience factors necessary for a successful coping process.

It is now believed that the cause of many mental disorders is a combination of: (1) severe and/or repeated childhood trauma, and (2) lack of a person who could provide the intersubjective foundation for mentalizing. Trauma, thus, does not have to lead to a mental disorder and will not do so in cases when there are adults ready to face and recognize the child's traumatic experience and offer help in thinking about it and overcoming it.

Is Trauma Treatable?

Not only is trauma devastatingly painful, but it is very expensive (for details see Dimitrijevic, 2015). Therefore, more and more effort is being put into treatment of its consequences.

We now know who the most helpful parents are: autonomously attached women who had experienced significant loss(es) that they managed to overcome (labeled "Earned Secure," as opposed to "Continuous Secure") were able to show the lowest frequency and intensity of frightening or frightful behavior, and proved to be most helpful to their children. Owing to their experiences of both traumatization and overcoming it, these mothers, more or less unconsciously, know what their children need and how to provide that.

A study comparing 88 different interventions, 7,636 parents, and 1,503 children revealed that there was a small but significant improvement *only* when programs were focused on improving parental capacity to accurately perceive and "translate" social signals contained in the infants' and children's non-verbal signals (Bakermans-Kranenburg, van Ijzendoorn, & Juffer, 2003).

Trustworthiness

Emily R. Bunnett

Swinburne University of Technology

The interest in trust across multiple disciplines (e.g. psychology, sociology, economics, business, and ethics) has created some confusion surrounding the conceptualizations of trust and trustworthiness and the distinctions and interactions between. Nevertheless, trust is commonly viewed as subsuming vulnerability to a trustee through expecting their behavior to be altruistic and personally beneficial. In comparison, trustworthiness is considered a multifaceted concept concerning the characteristics of the trustee, specifically, their ability, benevolence, and integrity in carrying out the agreed task with the aim of mutually benefiting the parties involved or aiding the trustor. The three facets of trustworthiness are, in turn, considered antecedents of trust, albeit only contributing toward a portion of trust, being insufficient to fully encapsulate the concept. Together ability and benevolence, and integrity capture the "can-do" and "will-do" aspects of trustworthiness, respectively. The ability component entails the knowledge and skills required to successfully complete a task and in organizational settings the social competence and general wisdom necessary to succeed, whereas benevolence and integrity concern whether or not the trustee will employ those skills in order to benefit the trustor (i.e. act in their best interest). Whereas benevolence refers to the degree to which the trustee wishes to do a good job for the trustor, regardless of any profit, reflecting how loyal, caring and supportive they are, integrity encapsulates how strongly the trustee is considered to be bound by moral and ethical principles or how honest, just and fair they are. Benevolence may, therefore, be seen as contributing an emotional viewpoint to the circumstance, whereas integrity instigates a more rational approach toward to the situation. Moreover, the ability (competence) and benevolence and integrity (warmth) components of trust and other social judgments have been acknowledged and proven across cultures (Collquit, Scott, & LePine, 2007).

The association between trust and trustworthiness may be best described by considering the fact that while the facets of trustworthiness are necessary yet insufficient for predicting trust, a person's' trustworthiness and others' ratings of their trustworthiness are strongly associated with their prior acts of trust and altruism, with high trustors tending to also be

more trustworthy and vice versa, possibly reflecting their greater likelihood to adhere to social standards of reciprocity (Fiske, Cuddly, & Glick, 2007).

This association between trust and trustworthiness also is important in the development of trustworthiness, with the most important predictor of developing a trustworthy nature being past experiences wherein a child has observed interpersonal relationships and interactions reliant on trust. The social learning theory also plays an important role in determining and understanding the approach that participants take in determining whether or not to trust another. Specifically, in order to obtain an indication of one's general trust behavior, experiments utilizing strangers provide the most appropriate means of gaining reliable information, with prior interactions and experiences with others greatly impacting their general willingness to render themselves vulnerable to the actions of others. Furthermore, individuals are likely to employ their previous experiences in similar circumstances in formulating their decision to trust or not trust another.

The Correlates of Trust and Trustworthiness

Individuals who are perceived as trustworthy tend to be wealthy, influential, have high self-esteem, educated, older, happy, well adjusted, respectful, sought out by others for both friendship and sexual interactions, honest, altruistic, less controlling, attractive, sincere, moral and warm. Furthermore, having an internal locus of control tends to provide a strong predictor of trustworthiness (Frost, Stimpson, & Maughan, 1978; Lenton & Mosely, 2011). Conversely, individuals who are manipulative, selfish and cynical are generally considered untrustworthy, as are those who belong to groups that are frequently subject to discrimination and stereotypical judgments, such as homeless individuals and minorities (Gunnsthorsdottir, McCabe, & Smith, 2002).

It is important to note that various models of trustworthiness view the concept as arising from and depending on a combination of factors, including one's personality and previous experiences, contextual cues and the other parties involved. However, trustworthiness has also been postulated as a personality facet that is developed early in life and remains relatively stable throughout one's life and across various situations. For example, the 16 Personality Factor Questionnaire, a broadly used and researched measure of personality, incorporates trustworthiness as one of the primary factors under the higher order "Anxiety" factor. Previous research has generally found that individuals often display high or low trait levels of trust, which is frequently linked to ratings of high and low trustworthiness, respectively. Nevertheless, the degree to which a person acts in a trustworthy manner may vary according to the potential gains they stand to receive from reciprocal relationships, their previous interactions with others or in similar situations and a myriad of other factors.

The Importance of Trustworthiness and Trust

Neuroimaging has confirmed the presence of an automatic neural system that is constantly scanning the environment to alert the individual to any potentially dangerous or harmful stimuli. Neuroimaging and lesion studies have both evidenced that the amygdala plays an

integral role in activating this system in response to potentially threatening stimuli, and have extended this to the realm of unconscious or automatic judgments of trustworthiness, occurring within 100 ms after exposure. Specifically, the amygdala has been found to provide the center for automatic assessment of facial cues in the search for facial properties commonly found to signal untrustworthiness, with the greatest level of activation occurring in response to cues of untrustworthiness (Engell, Haxby, & Torodov, 2007). Nevertheless, while activation in the amygdala reflects implicit judgments of trustworthiness, activation in the superior temporal sulcus reflects explicit judgments of trustworthiness and intention. The subsequent conscious judgment of trustworthiness provides idiosyncratic differences in individuals' judgments and hence modulates the effect that the amygdala has on behavior (Winston, Strange, Doherty, & Dolan, 2002). Furthermore, when trust has been built or identified, oxytocin levels rise but quickly diminish when the social cue of trustworthiness is terminated.

Judgments of trustworthiness are not only integral in identifying indices of potential threat; they also set the precedent for all social interactions, particularly those concerning social gain. Specifically, one of the most important factors in all social environments is determining whether a stranger can be trusted or not. An evolutionary aspect associated with the immediate detection of cues signaling trustworthiness is the tendency for people to aim to disprove others' trustworthiness. That is, we are more attentive to stimuli and features indicating that an individual should not be trusted, rather than searching for signs to prove that they may be trusted. This attentional bias acts to protect one from harm and from participating in detrimental relationships and is particularly strong in those considered to be low trustors (Gurtman & Lion, 1982).

Twin Studies and Personality

Breanna E. Atkinson and Philip A. Vernon

University of Western Ontario

Psychologists who study personality are interested in the nature and origins of individual differences or variations between people in personality traits and resulting behavior. Why, for example, are some people more extraverted or less conscientious than others? Many different theories about this and about the nature or structure of personality have been proposed since the scientific study of personality began in the early twentieth century. Notable among these is the Big 5 or Five Factor Model of personality, which suggests that the factors of Openness to Experience, Conscientiousness, Extraversion, Agreeableness, and Neuroticism are the major dimensions of personality, while other models have proposed the existence of additional personality traits that lie outside or beyond the theoretical space encompassed by the Big 5. These include the HEXACO (Honesty-Humility, Emotionality, Extraversion, Agreeableness, Conscientiousness, and Openness to Experience) and the Supernumerary Personality Inventory (SPI: Conventionality, Seductiveness, Manipulativeness, Thriftiness, Humorousness, Integrity, Femininity, Religiosity, Risk-Taking, and Egotism). The Dark Tetrad (narcissism, Machiavellianism, subclinical psychopathy, and sadism) is another example of a model of personality that extends beyond the Big 5 and there are numerous others. Some personality psychologists have also included attitudes and intelligence and other cognitive abilities in their theories.

Identical (or monozygotic, MZ) twins share 100% of their genes; fraternal (or dizygotic, DZ) twins share about 50% of their genes, on average, by descent. This difference between MZ and DZ twins makes twins a natural experiment which allows estimates to be made of the relative extent to which genetic and/or environmental factors contribute to individual differences in personality and other traits. Specifically, greater MZ than DZ resemblance indicates genetic influence on the trait(s) under study. Twin studies of personality are, thus, able to account for the major sources of variation between people.

The phenotypic (observed) variance in any given trait can be partitioned into additive and non-additive genetic variance and shared and non-shared environmental variance. Genetic effects are additive when the joint effect of alleles equals the sum of their individual effects. Non-additive effects occur when the joint effect is interactive or multiplicative.

Shared environmental effects refer to situations and events in a twin pair's environment that they have in common; for example, growing up in the same home, having the same parents, possibly attending the same schools and the like. Non-shared environmental effects refer to things that one twin experiences, but that his or her co-twin does not experience. Shared environmental events make twins alike whereas non-shared environmental events make them different. In twin studies, additive genetic effects, non-additive effects, and shared and non-shared environmental effects are customarily designated by the symbols a^2, d^2, c^2, and e^2, respectively.

Human behavioral genetics is the scientific field that studies twins and other genetically informative kinships in which "model fitting" estimates of a^2, d^2, c^2, and e^2 are made. To illustrate, one model might propose that individual differences in a personality trait can be attributed 40% to additive genetic effects, 40% to non-shared environmental effects, 10% to shared environmental effects, and 0% to non-additive genetic effects. These estimates are used to calculate the estimated MZ and DZ variances and covariances and these, in turn, can be compared to the actual variances and covariances obtained from data collected from twins. If there is no significant difference between the estimated and actual variances and covariances it is assumed that the model has a good fit. If a significant difference is found, the initial a^2, d^2, c^2, and e^2 estimates can be changed and a different model can be tested. Typically, a full A, C, E or A, D, E model is tested first (data from twins reared together cannot simultaneously test an A, C, D, E model) and then reduced models such as A, E, or C, E can be tested. An E only model may also be tested if only to show that this produces a poor fit; an E only model could only fit if there was no correlation between either MZ or DZ twins.

Johnson, Vernon, and Feiler (2008) reviewed over 50 years of behavioral genetic research that provided estimates of a^2, d^2, c^2, and e^2 for the Big 5 and related personality traits. In total, over 85,000 pairs of MZ twins and over 106,000 pairs of DZ twins had been given 83 different relevant personality tests and questionnaires; within studies the twin sample sizes ranged between 10 and 7,873 pairs. The key findings of this review were that individual differences in the Big 5 are largely attributable to additive genetic and non-shared environmental factors and that the contributions of non-additive genetic and shared environmental factors are small to negligible. Across all the studies, the median estimates of a^2, d^2, c^2, and e^2 were .45, .02, .12, and .49, respectively, for Openness to Experience; .41, .29, .11, and .52 for Conscientiousness; .48, .26, .03, and .49 for Extraversion; .37, .12, .17, and .54 for Agreeableness; and .41, .22, .06, and .59 for Neuroticism. Some of the studies in this review included pairs of MZ twins who had been separated at birth and raised apart with different adoptive parents. On all measures of the Big 5 the correlations between the reared-apart twins were somewhat lower than those among the reared-together twins, but they were also all larger than the correlations between unrelated adopted siblings when these were reported. This compares to the results of a study by Bouchard, Lykken, McGue, Segal, and Tellegen (1990) which reported that MZ twins reared apart were about as similar as MZs raised together on multiple measures of personality.

The finding that additive genetic and non-shared environmental factors make the largest contribution to individual differences in personality is not restricted to the Big 5. Numerous twin studies have reported the same results for virtually every personality trait that has been measured, including the HEXACO, the SPI traits, the Dark Triad, Trait Emotional

Intelligence, and others. In their classic textbook *Behavioral Genetics* (2008), Plomin, DeFries, McClearn, and McGuffin state that there have been no replicated studies reporting a zero heritability for any specific personality traits, and that environmental effects are almost always non-shared. Studies of attitudes and intelligence and mental abilities have reported that these are also heritable.

With respect to intelligence, it is informative to consider a new type of twin-like sibship, referred to as "virtual twins" (e.g. Segal, McGuire, & Stohs, 2012). Discovered by Nancy Segal, virtual twins are same-age, unrelated siblings who have been reared together with the same parents since infancy. Because they only share their environment their correlation provides a direct estimate of c^2. Segal et al. (2012) reported that the correlation between the IQs of 142 pairs of virtual twins is .28; this would estimate that the heritability of IQ is .72 which agrees with estimates derived from MZ and DZ twins raised together or apart.

Some twin studies have measured two or more personality traits in the same samples and these allow bi- and multivariate analyses to be conducted, which estimate the extent to which a phenotypic (observed) correlation between two or more variables is itself attributable to correlated genetic and/or correlated environmental factors. These analyses compute MZ and DZ cross-correlations: the correlation between one twin's score on one variable and his or her co-twin's score on another variable. To the extent that the MZ cross-correlation is larger than the DZ cross-correlation, this suggests the role of common genetic factors contributing to the phenotypic correlation between the variables.

Numerous multivariate twin studies have been conducted and, in much of this research, phenotypic correlations between different personality traits have been reported to be primarily attributable to correlated genetic factors and to a lesser extent to correlated non-shared environmental factors. Examples include studies that have measured twins on the Big 5 and the Dark Triad, the SPI and the Dark Triad, Trait Emotional Intelligence and Humor Styles, personality and intelligence, multiple factors of aggression, and different factors of antisocial personality disorder, to name a few.

In addition to studies of normal personality traits, twin studies have also focused on the contributions of genetic and environmental factors to the development of abnormal personality or psychopathology. These include studies of schizophrenia, mood disorders, anxiety disorders, autism, and ADHD.

Schizophrenia occurs in about 1% of the general population whereas the concordance rate is about 17% in DZ twins and 48% in MZ twins. These concordance rates clearly implicate genetic factors, but the fact that the MZ rate is less than 50% also means that non-shared environmental factors must also play a role; one such factor may be birth complications. At the same time, the fact that the children of discordant MZ twins are equally likely to develop schizophrenia, whereas among children of discordant DZ twins only those whose parent was schizophrenic are at much greater risk, again implicates the role of genetic factors.

There are two major types of mood disorder: unipolar (depression) and bipolar (depression and mania). Twin studies provide little evidence for the influence of genetic factors on less severe unipolar depression, but clearly implicate the contribution of genetic factors to severe unipolar depression and to bipolar disorder. For these, the concordance rates for DZ and MZ twins are 11% and 40% and 40% and 72%, respectively. Non-shared environmental factors are again implicated.

Anxiety disorders, which include phobias and obsessive compulsive disorder, are among the most common form of mental disorder, but are typically less severe than schizophrenia or major depression. Fewer twin studies of anxiety disorder exist and their results are less consistent: some studies have suggested a genetic influence while others have not. Overall, however, these and non-twin family studies indicate a moderate influence of genetic factors, possibly due to a genetic correlation between anxiety disorders and depression.

Twin studies of autism and ADHD clearly support the influence of genetic factors. The concordance rate for autism among MZ twins is about 60% (1,000 times greater than in the general population) while the concordance rate among DZ twins is lower. Twin studies of ADHD suggest a heritability of about 70%.

To conclude, a substantial amount of behavioral genetic research has been conducted on normal and abnormal personality over the past 60 or so years. Almost without exception, this research converges on the finding that the major sources of individual differences in personality are additive genetic and non-shared environmental factors. In contrast, non-additive genetic and shared environmental factors make a much smaller contribution. Twin studies of personality include MZ and DZ twins reared together or separated at birth and reared apart. Some theories of personality include intelligence and cognitive abilities, and intelligence has also been investigated in virtual twins.

Unconscious Processes, Expression of Personality Process

Aleksandar Dimitrijević

International Psychoanalytic University, Berlin

The unconscious was a very important topic in various scientific and cultural disciplines during the nineteenth century, especially in Germany and France. Philosophers, as well as poets, maintained that there must be a part of our personalities that we are not and cannot be consciously aware of. It was, however, through the work of Sigmund Freud and within domains of psychoanalytic theory that the unconscious became a scientific field of research, a focus of specific clinical treatment, and, eventually, a household word.

Today, we distinguish between three major dimensions of the unconscious (see Akhtar, 2009):

1) descriptive unconscious – recognition that some contents of psychic life are not accessible to conscious awareness, mostly present in cognitive ("general") psychology;
2) systemic unconscious – notion that one part of the human mind is organized according to certain principles, frequent in personality psychology;
3) dynamic unconscious – the unconscious "material" that influences our behavior, decision-making, dreams, symptoms, etc. which is the basic postulate of psychoanalysis.

Psychoanalytic Understandings of the Unconscious

Freud approached the unconscious as a therapist who realized that his patients' traumatic experiences were not accessible to them, but could be recovered from what we would call their long-term memory. He wondered where these memories were located in the meantime (between the traumatic event and the psychoanalytic session), and discovered that they played a crucial role in the creation of various forms of behavior.

For Freud, the unconscious was far larger and more powerful than the conscious. As this notion was in opposition to Cartesian *cogito*, Freud was first harshly criticized and then inspired many trends in twentieth-century psychology and philosophy. He believed he had discovered the mechanisms that ruled the unconscious, as well as mechanisms of the

mutual influence between the two parts of personality. Mental images in the unconscious may be combined into one (the mechanism of condensation); one image (or its parts) may represent the other (displacment); mental images may refer to something completely different yet very important to the person (symbolization). Freudian analysis is based on recognizing these three mechanisms in symptoms, dreams, slips of the tongue or pen, etc.

The unconscious is powerful because it is the seat of our most important sources of motivation, drives which, Freud believed, were the ultimate reasons behind our conscious decisions. We can try to react to their influence by employing our defense mechanisms, but we can never win this fight: defense mechanisms use up a lot of energy, yet can only change mental representations connected to drives (anger will not disappear, one may only be angry with another person, for instance). Conflict between the two parts was continuous and everlasting, Freud believed, and there was no way for the consciousness to win in the long run.

Alternative visions of the unconscious were elaborated during further development of psychoanalysis. The idea of the collective unconscious, originally formulated by Carl Gustav Jung to deal with similar unconscious images and notions ("archetypes") present in all members of the human race, is still influential, although it is not considered scientifically testable, maybe even not politically correct enough, while Erich Fromm described the social unconscious, which should be shared by all members of the same culture. The so-called object relations theory switched the focus from drives to inner, unconscious representations of social and physical objects, their interactions and influences. French theorist Jacques Lacan believed that the unconscious was structured as a language. Freud's pessimism was also replaced by theories of the unconscious as a possible source of creativity, authenticity, and playfulness. Finally, the unconscious was less and less seen as a depository of elements that were inborn, or occurred too early for us to be able to remember them or were repressed, but as a host of "unformulated experiences."

Regardless of the theoretical conception, clinical practice of psychoanalysts and many psychotherapists is focused on recognizing patterns of influence the unconscious exerts on the conscious. It is considered that the unconscious is revealed through dreams or slips, but even more so through the basic elements of the treatment process: transference (patient's projections onto the therapist), countertransference (therapist's projections onto the patient), and resistance (patient's unconscious subversion of therapeutic gain and improvement).

Empirical Research of the Unconscious

In the beginning, psychoanalysts followed Freud's predicament that "dreams [were] the royal road to the unconscious." This was based on clinical findings that mechanisms of and symbolization in dreams expressed unconscious wishes that were impossible to satisfy during the previous day. Then Jung discovered that association tests with reaction time measurement could empirically validate the influence of the unconscious. The so-called projective techniques of psychological assessment were all based on this assumption: if you show your subjects unstructured stimuli, like Rorschach ink-blots, they will give it a structure in their minds, expressing along the way and without being aware of it some of their unconscious wishes and fears.

In the domain of empirical research, the unconscious is, to put it most succinctly, not a noun, but an adjective. Researchers do not aspire to describe a personality instance, but

only processes that occur outside our conscious awareness. For this they use three basic methods: studying subliminal perception; using psychophysiological methods, like event-related potentials (ERP); and experimental procedures (for details see Shevrin, Bond, Brakel, Hertel, & Williams, 1996).

Empirical research of the unconscious is very widespread, so much so that some of its facets make up the core of contemporary cognitive psychology. Probably the best example of this is the so-called Dual Process Theory. Proponents of this approach, very prominent in social and cognitive psychology, hold that there are cognitive processes that are fast, automatic, and implicit (unconscious), as well as those that are slow, controlled, and explicit (conscious). This distinction, proven in laboratory experiments and fMRI scannings, was elaborated by Freud more than a century ago in the description of "primary process" (which governs the unconscious) and "secondary process" (typical of consciousness). "Cognitive unconscious" is, thus, very similar to an empirically more disciplined version of psychoanalysis, which rarely studies the influence of non-cognitive variables (emotions, drives, fantasies) on cognition.

The existence of unconscious complex psychological processes is hardly doubted by mainstream cognitive science. There are many findings, for instance, about how exposure to visual or verbal stimuli at such speeds that the subjects are not aware of seeing them influences subsequent behavior. This procedure, called priming, may induce anxiety and lead to impulsivity, worse results on simple cognitive tasks, or change in attitudes.

Evidence for unconscious processes is so overwhelming that Shevrin and Dickman's starting question "what behavior requires a conscious decision and what behavior does not" (1980) has recently been resoundingly answered: "Behavior does not originate with a conscious decision" (Dijksterhuis et al., 2007; after Baumeister, Masicampo, & Vohs, 2011), because "most and possibly all human behavior emerges from a combination of conscious and unconscious processes. Nothing we have reviewed would prove that any behavior emerged from exclusively conscious processes" (Baumeister et al., 2011). For instance, participants in one experiment watched a highly precise clock and recorded when they made a conscious decision to move a finger; brain wave activity, however, showed a sharp increase prior to this decision, and this is believed to be evidence for the importance of unconscious decision-making. It is now generally assumed that conscious intentions (1) signal the direction of action, (2) cannot cause the action, (3) can stop an action.

It was also asserted that the unconscious has superior capacity and makes better, more logical choices and decisions: "contrary to popular belief, decisions about simple issues can be better tackled by conscious thought, whereas decisions about complex matters can be better approached with unconscious thought" (Dijksterhuis & Nordgren, 2006). Furthermore, some researchers asserted that "strictly speaking, conscious thought does not exist, because what seems to be conscious thought is merely some calculations performed unconsciously that happen to cross into awareness" (Baumeister et al., 2011).

And there are also those bold enough to furnish a precise numerical estimate: "Our psychological reactions from moment to moment [...] are 99.44% automatic" (Chen & Bargh, 1997).

To summarize, empirical findings about the unconscious processes reveal: (1) that some psychological processes are unconsciously performed and causally determine conscious processes, (2) that they are governed by their own cognitive rules, (3) that they set out their own intentions, (4) and that they lead to a conflicting organization of psyche (after Arminjon, 2011).

Mihaly Csikszentmihalyi

Hans Henrik Knoop

Aarhus University

Milhaly Csikszentmihalyi is the C. S. and D. J. Davidson Professor of Psychology at the Peter F. Drucker Graduate School of Management at Claremont Graduate University and founder and co-director of the Quality of Life Research Center there. The center is a non-profit research institute that studies "positive psychology"; that is, human strengths such as optimism, creativity, intrinsic motivation, and responsibility. In 2008, the center launched the world's first doctoral programs in Positive Psychology. Csikszentmihalyi is a member of the American Academy of Education, the American Academy of Arts and Sciences, and the National Academy of Leisure Studies. In 2009, he was awarded the Clifton Strengths Prize and received the Széchenyi Prize, the Hungarian national science prize, in 2011. He is also emeritus professor of human development at the University of Chicago, where he is former chair of the Department of Psychology, and he holds honorary doctorates of science from Colorado College and from Lake Forest College, and a doctorate of fine arts from the Rhode Island School of Design. He is the author or co-author of more than 15 books and some 250 research articles.

Milhaly Csikszentmihalyi was born in Fiume, Italy (today Rijeka, Croatia), on September 29, 1934. His family was from Hungary, and his father worked as Hungarian diplomat to Italy. Csikszentmihalyi grew up in Italy with World War II deeply disrupting his and his family's life. While still a child, he was held in an Italian prison camp outside Rome, where his parents worked. During the war, many of his relatives and friends in Budapest were killed. One of his brothers died in combat, and another was sent to forced labor camp in Siberia by the Russians. While experiencing the war, several insights became particularly formative for the young Mihaly: he was struck by how he was able to immerse himself in a game of chess for hours even though the world around him was in flames; he was disappointed by the adult generation's obvious incompetence in protecting what is most important in life and giving in to mass delusions, notably brought about by the propaganda of Hitler and Mussolini; and he found inspiration in psychological approaches, such as Carl Gustav Jung's, to do something about it. Csikszentmihalyi immigrated to the United States in 1956 at the age of 22 to study psychology at the University of Chicago where he received his BA in 1960 and his PhD in 1965. He is married to the writer Isabella Selega with whom

he has raised their two sons, the artist and technologist, Christopher Csikszentmihalyi and the professor of philosophical and religious traditions of China and East Asia Mark Csikszentmihalyi.

Milhaly Csikszentmihalyi is one of the most influential developmental psychologists living today. He is best known for the theory of flow as an expression of optimal experience (Csikszentmihalyi, 1990). He also pioneered the influential experience sampling method on which much of the empirical work on flow is based (Hektner, Schmidt, & Csikszentmihalyi, 2007). Following the huge popularity of his book "Flow – the Psychology of Optimal Experience" (1990), he developed the broader systems theory of the emergence of the self, which promotes the idea that modern human beings should take fuller responsibility for their personal actions and their environments through increasing self-awareness and control of consciousness, thereby freeing themselves of excessive genetic, cultural and selfish constraints. This theory was laid out in the magnum opus, "The Evolving Self," subtitled "A Psychology for the Third Millennium" (1993), by which important intellectual and synthesizing headway was made toward what would a few years later become "positive psychology." For more than a decade, in collaboration with psychologists Howard Gardner and William Damon, he led the GoodWork Project aimed at understanding how leading professionals do work that is at the same time engaging, excellent, and ethical (e.g. Gardner, Csikszentmihalyi & Damon, 2001; Csikszentmihalyi, 2003), and with Martin Seligman he co-founded the field of Positive Psychology (Seligman & Csikszentmihalyi, 2000; Csikszentmihalyi, 2014), which has since become what may be viewed as an empirically strengthened humanistic psychology.

The contributions by Milhaly Csikszentmihalyi to our understanding of human motivation, enjoyment, creativity, community building, and ethics have had an impressive appeal throughout the world. Artists, educators, business people, athletes, and many other professions continue to be inspired by his work. Thus, half a century after the initial works on flow theory, and almost two decades after the inception of Positive Psychology, he stands as one of the brightest beacons of psychology, potentially enlightening any domain of human interest for generations to come.

Jeffrey A. Gray

James Kean

Swinburne University of Technology

Background

Jeffrey Gray was a renowned British experimental neuropsychologist from Oxford University who made remarkable contributions to the field of neuropsychology of emotion, personality, anxiety, and schizophrenia. Born May 26, 1934 in East London, Gray was primarily raised by his mother following the passing of his father when Gray was 7. As a child, Gray attended Ilford County High School for Boys where he undertook studies in Latin, Greek, and history, even taking home the title of school boxing champion. He joined the military in 1952 and during his years of service, taught himself to speak Russian, a skill in high demand from Army intelligence. His completed his military service in 1954 and continued to pursue his love of languages, going on to learn French, Spanish, Italian, and his wife Venus' native language of Persian. Outside the laboratory, Gray greatly enjoyed the arts, and once directed a production of *The Winter's Tale* in the Deer Park at Magdalen College. For the lead role of *Autoycus*, Gray came across a very talented young actor and decided to give him the role; that young man was Dudley Moore. Gray and Venus had four children, Ramin, Babak, Leila, and Afsaneh. On April 30, 2004, Jeffrey Gray died following a long battle with illness.

Academic Career

In 1955, Gray was awarded a MacKinnon scholarship to Magdalen College in Oxford to study law. However, his career in law was short-lived and Gray moved away from law to study modern languages, and was awarded the highest grade in Spanish and French. Following the successful completion of his first degree, Gray went on to complete a second degree in psychology and philosophy in 1959. He trained as a clinical psychologist and received his PhD in 1964 for his work on the emotional behavior of animals at the Institute of Psychiatry at King's College in London, which at that time was headed by renowned intelligence and personality psychologist Hans Eysenck. On one occasion, Gray acted as

Eysenck's Russian translator at a conference in Moscow in 1966. It was there the two met Marvin Zuckerman, a renowned psychologist in sensation seeking and personality. This academic comradeship would last the rest of both Gray's and Eysenck's lifetime.

In 1964, Gray worked as a lecturer within the Department of Experimental Psychology at Oxford University and was subsequently awarded an associate tutorial fellowship at University College in 1965. After 19 years at Oxford, Gray returned to the Institute of Psychiatry at King's College in London and became Hans Eysenck's successor as chair of psychology. Gray held the position of chair until his retirement in 1999, but continued his research in experimental psychology as an emeritus professor within the Center for Advanced Study in the Behavioral Sciences at Stanford University, California from 2001 to 2002.

Major Contribution: The Biopsychological Theory of Personality

Gray's work in the field of personality has been fundamental in the understanding of the biological mechanisms that underlie personality and individual differences. His interest in the functionality of the septohippocampal region led to one of his most significant contributions to science – *the biopsychological theory of personality*. Gray began his academic studies at the Institute of Psychiatry headed at the time by Hans Eysenck, a prolific German-born English psychologist whose theories regarding the foundations of personality Gray would later go on to contradict, citing his own biopsychological explanations. Both theorists cited specific neural activation to explain personality – Eysenck proposed the *ascending reticular activating system* (ARAS) led to specific behaviors based on stimulation or arousal, and Gray proposed the *behavioral inhibition/activation system* (BIS/BAS) that led to specific *approach* or *avoid* behaviors based on reinforcement signals. Gray's theory states that people will assess any given situation and based on previous experience, their behavior will either be to approach that situation (*appetitive motivation*) or avoid it (*aversive motivation*). The underlying mechanisms for each system are neurologically diverse, which differentiates Gray's biopsychological theory of personality from Eysenck's. The aversive actions of the BIS are linked to activation within the septohippocampal region including its brainstem-derived afferent monoaminergic pathways and neocortical projections to the frontal lobe. This system leads to the inhibition of action toward goals, and is composed of negative feelings such as fear, anxiety, frustration, and sadness. The BAS is more closely tied to the actions of the mesolimbic catecholaminergic pathways, specifically dopaminergic pathways, which are strongly linked to the brain's reward and punishment systems. This system is composed of positive feelings such as hope, elation, and happiness. Together the systems work in an antithetical manner, meaning a person may approach a given situation with either system depending on their individually reinforced moderating factors.

Gray's theory proposed two personality dimensions key to these approach and avoid actions – *impulsivity* and *anxiety*, which can be roughly paralleled with Eysenck's original personality dimensions for *Extraversion* and *Neuroticism*, respectively. Gray's and Eysenck's theories approach the concept of personality from opposite ends; as psychologist Marvin Zuckerman once noted, "Eysenck (1967) was an exemplar of the top-down approach and Gray (1982) is one for the bottom-up approach." There are many advocates for Gray's biopsychological theory of personality, however, many believe the theory is so highly

specific that it only truly encompasses a small range of behaviors, limiting its overall scope to a narrow portion of human behavior.

Major Contributions to Anxiety

In collaboration with Neil McNaughton (University of Otago, Dunedin, New Zealand), Gray published the controversial, yet historically significant book *The Neuropsychology of Anxiety*. The text was quickly established as essential for neuropsychologists, and earned itself the "instant classic" label despite the controversy surrounding the newly posited theories of anxiety and their underlying mechanisms of action. Gray posits that the role of the septohippocampal network is to detect conflict between two goal states: *approach* and *avoid*. The number of conflict combinations can therefore be easily noted: *approach-approach*, *approach-avoid*, and *avoid-avoid*, which are acted upon depending on the moderating factors involved. It is this competition of decision-making that Gray documented as a possible neurological explanation for symptoms of anxiety. In an updated edition of the book (2000), Gray and McNaughton support previous evidence for the role of the septohippocampal network in anxiety, noting that anxiolytic drugs produce similar effects to septohippocampal lesions on outcomes for behavior and memory function.

Major Contributions to Schizophrenia

In 1991, Gray and colleagues proposed a neuropsychological model for schizophrenia. Derived from extensive clinical and experimental data from various fields of investigation, Gray was able to provide one of the most complete neuropsychological explanations for schizophrenia the scientific world had seen up until that time. Gray and his team utilized "postmortem neuropathology and neurochemistry, clinical and preclinical studies of dopaminergic neurotransmission anatomical connections between the limbic system and basal ganglia, attentional and other cognitive abnormalities underlying the positive symptoms of schizophrenia, specific animal models of some of these abnormalities, and previous attempts to model the cognitive functions of the septohippocampal system and the motor functions of the basal ganglia." With this abundance of data and empirical evidence, Gray published the now infamous The neuropsychology of schizophrenia, a chapter within the book *Biological Psychiatry* published in 1991. This massive collection of data allowed Gray to report a neurological dysfunction between past and present associative memories related to positive symptoms with acute schizophrenia, and this neuropsychologically distinct theory identified why persons with the disorder have difficulty processing new information.

Other Notable Works

In 1971, Gray published the innovative *The Psychology of Fear and Stress*. It was noted as an extremely interesting theory that discussed the mediation of anxiety and the fear responses in the brain. The work discusses neurological responses to particular environmental

demands, with a preponderance animal experimental research allowing greater insight in pathological samples. The book was praised for its accessibility not only to clinicians, but to university student and layman readers interested to learn about the biopsychological response to everyday stresses. In 1987, Gray published the second edition of the book, adding significant amounts of empirical evidence from a decade of research to update his neuropsychological theories on emotion, anxiety, fear, and stress.

In 1975, Gray wrote *Elements of a Two-Process Theory of Learning*. The text discusses the two-process theory of learning, which argues that animal learning consists of classical and instrumental conditioning. The book goes on to examine underlying mechanisms for emotional learning in humans and the intricate ways the human personality is structured.

Acknowledgments and Awards

Jeffrey Gray was one of the leading experimental psychologists in the United Kingdom. Part of his 1964 PhD thesis was published as a book, *Pavlov's Typology; Recent Theoretical and Experimental Developments from the Laboratory of B. M. Teplov*. It was an English translation of key work conducted in Russian laboratories and was praised as "...the best exegesis and clarification of Russian work to be produced by any western psychologist" (Professor Stuart Sutherland, Oxford University). Gray received the president's award from the British Psychological Society in 1983 and was made an Honorary Member of the Experimental Psychology Society in 1999.

Conclusion: Personality and Individual Differences

Jeffrey Gray's significant contribution to the field of neuropsychology has enabled a generation of clinicians to understand the neurological mechanisms that underlie human personality and individual differences. The breadth of evidence Gray vigilantly assembled and examined in each of his works is a testament to his commitment to the science of neuropsychology.

Owing to the dynamic nature of the field, Gray's contribution has significantly enhanced the foundations of personality and individual differences research, allowing clinicians to use neurological and neurochemical explanations for various personality traits. Overall, Gray's contributions to the biopsychological mechanisms in personality, anxiety, emotion, and schizophrenia have provided the groundwork for future research in personality.

Douglas N. Jackson

Sampo V. Paunonen[†1] and Richard N. MacLennan[2]

[1] *University of Western Ontario*
[2] *University of Regina*

[†]*Deceased*

Douglas Northrop Jackson was a psychologist renowned for his contributions to personality assessment and psychometrics. He was born on August 14, 1929, in Merrick, New York. He first completed his Bachelor's degree in Industrial and Labor Relations at Cornell University in 1951. He then chose to follow other interests in graduate school and registered in the Clinical Psychology program at Purdue University. There he completed his Master's degree in 1952, followed quickly by his doctorate in 1955 under the tutorship of John M. Hadley. While he was enrolled in the doctoral program at Purdue, Jackson did an internship at the Menninger Foundation in Topeka, Kansas, under Gardner Murphy (1953–1954). He continued his work there as a postdoctoral fellow (1955–1956). Murphy was to have a huge influence on Jackson's intellectual thinking and research direction. It was also during those early years that Jackson decided that he was not cut of a cloth suitable for clinical practice, and his research interests began to turn in the direction of personality assessment. Jackson spent most of his professional career at the University of Western Ontario, in London, Ontario, Canada (1964–1996).

Although Jackson's earliest publications were in the area of clinical psychology, he began a productive collaboration with Samuel Messick in the late 1950s and, together, their interest turned to standardized methods of psychological assessment. In particular, Jackson and Messick were intrigued by the thinking process involved in a test respondent's decision to choose one response option over another in completing the items of a personality questionnaire. They came to the realization that accurate self-reports to such items could be seriously compromised by what they called response styles. A response style is a characteristic approach to item responding that involves a bias for preferring some types of item alternatives over others. One such response style or bias studied by Jackson and Messick is called acquiescence, or the preference for the true, yes, or agree response options where available. Another response bias, which has a prominent place in the assessment literature even to this day, is socially desirable responding, or the tendency to prefer the more desirable

response option to an item where available. Jackson and Messick's research on response styles resulted in one of their most influential works, called "Content and style in personality assessment," published in *Psychological Bulletin* in 1958. In that article, the authors emphasize the need to develop personality scales that actively control for the various response biases that can negatively impact on a measure's accuracy or validity.

Jackson's interest in personality assessment accuracy was more general than that related simply to response styles. Much of his thinking and research in the 1960s and beyond involved philosophical issues about the very meaning of the personality test item response. Inspired by theoreticians such as Cronbach, Loevinger, and Meehl, Jackson firmly believed in the importance of test item content, and the relation of that content to some theoretically based personality trait or construct. This idea is basic to the construct-based method of personality scale construction, where one begins with a well-defined nomological network of interrelated personality traits and writes test items that describe behaviors and beliefs that are prototypes or exemplars of the trait being measured. This strategy of test design, championed by Jackson, is starkly different from the older criterion-based approach preferred by some, whereby item criterion predictive power rather than item content is considered the ultimate metric by which a test item should be judged. Jackson eschewed criterion-based methods of test design, mostly because the resultant test scores can have no psychological meaning. His views on test construction are most eloquently expressed in (1) his seminal statement on the theory and practice of personality assessment, published in *Psychological Review* in 1971, called "The dynamics of structured personality tests: 1971," and (2) his development and publication of several well-regarded personality questionnaires, the most famous being the Personality Research Form and the Jackson Personality Inventory. He spent a large part of his career gathering and publishing empirical evidence of the superiority of construct-based approaches to personality assessment over other approaches.

Jackson and many of his students shared an avid interest in person perception and, in particular, the accuracy of people's ratings of personality. This area of research has an obvious connection to personality assessment for two reasons. First, self-reports on personality items can be seen as a special case of person perception, where the target is the informant on him or herself, so many of the issues involved in the accuracy of peer ratings of personality apply to self-ratings of personality. Second, peer ratings of personality are often used as a criterion by which self-rating scales are validated, so anything that can affect that criterion can in turn affect test validation results. Jackson was a strong believer in the accuracy of self-reports of behaviors and beliefs, and in the corroborating judgments made by well-acquainted informants. This area of his research was instigated primarily as a response to Walter Mischel's attack on personality assessment, in a book entitled *Personality and Assessment* (1968). More fundamentally, the research was consistent with Jackson's fervent belief in the existence of personality traits and, consequently, in the general consistency and predictability of behavior, two ideas that are at the very foundation of construct-based personality assessment. Much of the related theorizing and empirical research was summarized by Jackson and Paunonen in an *Annual Review of Psychology* article published in 1980.

Jackson took a very early interest in computer applications in psychology, having written a book chapter on problems in computer models of personality back in 1963, long before the advent of the personal computer revolution. In his research lab, he was an early adopter of new microcomputer technology when it first became available, including the Radio

Shack TRS-80, Osbourne 1, IBM PC and AT, Toshiba Laptop, and Apple Macintosh. The first computer applications that Jackson implemented were writing programs to score and generate interpretative reports for his own personality inventories. Importantly, he felt that such computer-generated interpretative reports should be validated themselves, just like the tests on which they were based. Jackson also recognized the potential for computers to be used for the administration of both personality and cognitive tests, realizing their utility for advancing new developments in psychological assessment such as tailored testing. He also appreciated the computer's ability to collect important ancillary test data such as response latencies, which could yield valuable additional information on the respondents' cognitive abilities and even personality characteristics (MacLennan, Jackson, & Bellantino, 1988). Jackson was appointed as the American Psychological Association representative to the International Testing Commission, where he played a role in formulating their initial ethical guidelines for computer-based psychological assessment.

A passion for psychometric issues and the advent of user-friendly computer technology meant that Jackson and his students were able to make significant quantitative contributions to personality theory and assessment. Many of these endeavors involved the creation of sophisticated statistical algorithms. For example, he developed indices of person reliability, used to detect careless responding to psychological test items. He offered us the Item Efficiency Index, which represents the degree to which a test item is saturated with its own trait content and is independent of content related to irrelevant traits or to desirability. Jackson was aware of the importance of factor analysis to test construction, so he worked on a variety of problems related to (1) determining factor reliability, (2) developing techniques for multitrait-multimethod evaluations, (3) estimating the accuracy of different factor extraction methods, and (4) simplifying techniques for factor rotation such as Procrustes and Univocal varimax transformations. Also, in the area of person perception, he did some innovative work by applying person characteristic curves to judgments people make about others, and then relating the slope and threshold of an individual's curve to the psychological processes that underlie that person's perceptions of others.

In his later years, Jackson's research interests returned to his very earliest roots in industrial-organizational psychology, in which he did his Bachelor's degree. In fact, Jackson was instrumental in establishing the graduate I/O program at Western University, designed so that students could intern in business organizations, government, and non-government agencies, thus gaining both practical work experience and important resources for their graduate research. But, beyond this, Jackson left an indelible imprint in I/O psychology. In particular, he argued forcefully for applying sound psychometric principles to solving some of the problems in I/O psychology, most notably in the area of personnel selection and productivity. He strongly believed that personality measures had a critical role to play in matching the right person to the right job, but that previous research had failed in this endeavor by using inadequate psychometric tools (Jackson, Tett, & Rothstein, 1991). Another area in which he contributed important research was on the significant function that person perception had in the employment interview. Through several experimental studies, he was able to show that both lay people and professional personnel managers alike had an implicit, and consensual, understanding of the congruency between certain personality characteristics and related occupational roles. The data supported Jackson's belief that a well-designed structured interview could be an effective personnel selection tool in maximizing employee productivity and satisfaction.

Douglas Jackson was the founder of Research Psychologists Press and Sigma Assessment Systems, the publisher of some 20 of his own tests and questionnaires related to personality, psychopathology, cognitive abilities, and vocational interests. His substantial contributions to psychology have been well recognized. In 1997, he was awarded the Saul Sells Award for Lifetime Contributions to Multivariate Behavioral Research from the Society of Multivariate Experimental Psychology. He was elected President of APA's Division of Measurement, Evaluation, and Statistics (1989–1990), as well as President of the Society of Multivariate Experimental Research (1975–1976). He was nominated as Chair of APA's Committee on Psychological Tests and Assessments, and served as a member of the Executive Council of the International Test Commission. In 1989, he was elected Fellow of the Royal Society of Canada. Before his death, Jackson was honored with the 2004 Samuel J. Messick Award for Distinguished Scientific Contributions by Division 5 of APA. Douglas N. Jackson passed away on August 22, 2004 in his home in London, Ontario at the age of 75.

John F. Kihlstrom

James Kean

Swinburne University of Technology

Background

John F. Kihlstrom was born on October 24, 1948, in New York to Waldo and Harriet Kihlstrom. He was the youngest of three children with older siblings Donald and Jean. As a child, John assisted his mother in the proofreading of psychological reports for children at school with educational difficulties. It was this job that provided John with his initial drive to become a personality psychologist when he grew up.

Kihlstrom began his education at Colgate University, in 1970. During a course taught by William Edmonston, Kihlstrom found exactly what he was looking for, a mentor in personality psychology. It was here Kihlstrom took on a role as a Research Assistant within the Hypnosis Research Laboratory, eventually completing his Bachelor of Arts in Psychology with High Honors. From here, Kihlstrom moved to the University of Pennsylvania to begin his PhD within the Program of Research Training and Experimental Psychopathology. Kihlstrom requested to spend his time there continuing to investigate hypnotism and so he took on the role of Research Assistant for the Unit for Experimental Psychiatry where he began research in posthypnotic amnesia, and then moved into researching memory and consciousness. He was awarded his PhD in Personality and Experimental Psychopathology in 1974 and received the Henry Guze Award for best research paper in the field of hypnosis, titled "Posthypnotic amnesia as disrupted retrieval" by the Society for Clinical and Experimental Hypnosis. Kihlstrom then took on the role of Research Associate in 1974 and finally as a Research Psychologist in 1975, at the Unit for Experimental Psychiatry, The Institute of Pennsylvania Hospital.

Kihlstrom was appointed to an assistant professorship at Harvard University in 1975, within the Department of Psychology and Social Relations teaching psychological assessment. During his time, he was invited as a visiting professor to Stanford University within their Department of Psychology between 1977 and 1978. In 1980, Kihlstrom was promoted to associate professor at Harvard. His work during this time led to an American Psychological Association Early Career Award for his work in personality in 1979.

Kihlstrom moved from Harvard to a tenured position as associate professor at the University of Wisconsin in 1980. While there, Kihlstrom also took on a role of a visiting scholar at the Center for Cognitive Science at the University of Michigan. He was appointed professor in 1984 and was awarded the H. I. Romnes Faculty Fellowship from 1984 to 1987 and spent time as a Visiting Fellow at the School of Behavioral Sciences in Psychology at Macquarie University in 1986. Kihlstrom went on to teach courses in personality within the Department of Psychology at the University of Arizona from 1987 to 1994, and then at Yale within the Department of Psychology in 1994, as well as holding a fellowship at Silliman College. Finally, Kihlman began his position as professor at the University of California, Berkeley in 1996.

During his time at the University of Wisconsin, Kihlman met his current wife Lucy Canter. He continues to collaborate with her, in the field of health, cognition and behavior.

Major Contribution: Consciousness and Personality Assessment

Beginning in the 1950s in response to what psychologists deemed the "dark years of radical behaviorism," when subjects such as cognition and personality assessment were deemed unworthy of scientific study and therefore rarely found in the curriculum, there began a *cognitive revolution*. This revolution focused specifically on the mechanisms of the mind, whereas behaviorism ignored such things, and investigated the mental structure of cognition and its responses to the environment. In a recent paper, Kihlstrom references Hermann von Helmholtz's viewpoint that an individual's conscious experience of the world is influenced by *unconscious inferences*. This concept, that our thoughts and interactions with the environment are (at least in part) controlled by unconscious forces, was also investigated extensively by Sigmund Freud. These works spurred on Kihlstrom's primary theory that cognitive processes exist that operate outside of conscious thought. Kihlstrom focused on what he called the *cognitive unconscious*, an integral moment of information processing where incoming sensory information and the stored memories of that individual collide in a moment of neural collaboration. This moment produces a series of complex and interrelated unconscious processes that create a context for which that person perceives and behaves in that environment. One example Kihlstrom provides regarding *automatic processing* describes how people may assess one person's face as pleasant and another's as less so but would be at a loss to explain why this difference exists. These processes, he explains, cannot be explained by any psychological unconscious, but by a cognitive unconscious. Kihlstrom highlights the difference between the automaticity of procedural knowledge and the similarly implicit nature of what he denotes as a *preconscious declarative knowledge structure* which, in particular circumstances, is accessed below the threshold of conscious awareness that enables a uniquely individual perception of the environment. Kihlstrom succinctly describes this entire process stating "episodic memory is autobiographical."

During his time at Harvard, Kihlstrom taught graduate courses in psychological assessment with specific academic texts relating to personality, its assessment, and its predictability, as well as comprehensive introductions to diagnostic testing. Kihlstrom regarded personality as an integrated element of an individual's interaction with their environment,

rather than a separate dimension. In a unique case study in 1996, Kihlstrom and colleagues were able to establish that despite the (temporary) loss of episodic memory in a patient (W. J.), the patient's understanding of their own personality remained consistent. They could identify their "self" in personality terms, without the need for episodic memory. This case study indicates the complex nature of the self and the way in which that knowledge is organized in the brain.

Kihlstrom posits that the resulting behavior should be considered as *reciprocal determinism*, a combination of factors that include interactions between a person and their behavior, that behavior and the environment, and that person and the environment.

Major Contributions to Hypnosis

During his early career, Kihlstrom was also exposed to the research and psychology of hypnosis. During his PhD at the University of Pennsylvania, Kihlstrom published a number of papers pertinent to his dissertation regarding the subject matter of posthypnotic amnesia, memory, retrieval, and consciousness. After receiving his PhD and adopting the practice of hypnosis into his research, he hypothesized that hypnosis allowed therapists to gain insight into the *cognitive unconscious* of an individual. He posits that hypnotic studies provide insight into the distinct differences in episodic and semantic memory and intuitive problem solving. Kihlstrom's primary theory was around *posthypnotic amnesia*. His research investigated subjects in amnesic states, by asking them to recall items presented to them during times of hypnosis at a number of time-points. The inability to recall the items demonstrated successful amnesia; however, once a reversible cue was presented to them, the items could be recalled. Kihlstrom's work illustrates that there are mechanisms that memorize the presenting items despite the hypnotic state and others that repress that memory once they have returned from it. This is the finding that there exists a dissociation between episodic and semantic forms of declarative memory. The process of hypnotism impairs episodic memory such as *free recall*, but spares semantic memory such as *word association*.

Kihlstrom has also demonstrated that the effect of hypnosis upon a person's *perception* of a medical issue, rather than the issue itself, may alter the way that individual experiences any associated pain. This work led to publications exploring the nature of altered states of consciousness and cognition as well as the possibility of how children may form an understanding of theory of mind.

Other Notable Works

In the mid-1980s, Nancy Cantor and John F. Kihlstrom began work on a textbook about personality, cognition, and social interaction. This work formed the foundation for their theory of social intelligence in personality and was eventually published in 1987 in a book titled *Personality and Social Intelligence*. He has since published texts on basic behavioral science research for mental health in 1998, autobiographical memory (2009), social neuroscience (2010), unconscious processes (2013), and the most recent book titled *The Person–Situation Interaction* in 2013.

Acknowledgments and Awards

Kihlstrom received the Phil R. Miller Award in Psychology in 1970 followed by the Sherry K. and Harold B. Crasilneck Award in 1973 and the Henry Guze Award in 1974 for the Best Research Paper in the field of Hypnosis. Kihlstrom received both the Distinguished Scientific Award for an Early Career Contribution to Psychology and the *APA* Early Career Award in Personality in 1979. He received the Arthur Shapiro Award for Best Book in the Field of Hypnosis, as well as the Morton Prince Award for distinguished contributions to the development of hypnosis, both in 1980. He received the award for Best Theoretical Paper in the Field of Hypnosis for "Conscious, Subconscious, Unconscious: A Cognitive Perspective" in 1985, again in 1988 for the "The Cognitive Unconscious" and again in 1994 for "The Self-Regulation of Memory."

He was also elected to the Society of Experimental Psychologists as well as Richard and Rhoda Goldman Distinguished Professor in the Division of Undergraduate and Interdisciplinary Studies. He is a Fellow for the American Association for the Advancement of Science and the American Psychological Association. He has also received commendations for distinguished teaching at Yale University in 1997, an editorial service award as editor of Psychological Science from 1995 to 1999, for his contributions to the history of hypnosis in 2008 and for the best paper on a historical topic on Hypnosis in 2011.

Conclusion: Personality and Individual Differences

John F. Kihlstrom's work significantly contributed to the field of personality from the cognitive perspective and provided distinct insights into the conscious, the subconscious, and the unconscious. His work in hypnosis and its relationship to the cognitive unconscious inspired a new way of understanding how people store information below the conscious threshold. These unconscious memories create the individual differences seen in personality and the multiple ways in which people respond to their environment.

Salvatore R. Maddi

Salvatore R. Maddi

University of California, Irvine

The son of poor Sicilian immigrants, Salvatore Maddi was the youngest of his parents' four children, and the only male. Born in 1933, he grew up in the upper east side of Manhattan (New York) in what was then a gang-infested, immigrant neighborhood. His parents and sisters all saw him as the hope of the family, encouraging him to do well in school, so that he could make something of himself. Fortunately, Maddi's commitment to learning in school opened up his teachers to him, as most of the other boys were gang members, and were in school only because they had to be. His teachers tried to convince him that he was intelligent, and encouraged him to go to college and beyond.

When, at the end of his second year at Brooklyn College, he was forced to designate a major, all he could do was decide on Psychology, as his only A up to that point was in the required introductory psychology course. Once he designated that major, the psychology professors (who included Wayne Dennis and Edward Girden) took him under their wings, and his grades flourished enough for him to graduate with honors.

With the encouragement of the Brooklyn College psychology teachers, Maddi applied to and was accepted into and financed by the PhD program in the Department of Social Relations at Harvard University. There, he was very much influenced by Gordon Allport, Jerome Bruner, and David McClelland. Maddi served on the research teams of the latter two professors. His PhD dissertation was supervised by McClelland, and he received in 1960 a PhD with Honors in Personality and Clinical Psychology.

Receiving several academic job offers, Maddi became in 1959 an assistant professor at the University of Chicago. He taught and did research, counseling, and consulting there for 27 years, as he rose up through the ranks, becoming a full professor. He taught personality and clinical courses, and supervised many graduate students who have made their own contributions to psychology. Then, in 1986, he transferred to the University of California, Irvine, where he is still undertaking all these activities, and has also added consulting work and expert witnessing in civil rights lawsuits. He has won various awards at both universities. In his career, he has published many articles and books. He is also a Fellow of the American Psychological Association, and several of its Divisions. In addition, he is a Fellow

of the Society for Personology, the American Psychological Society, the Communitarian Network, the American Society of Bariatric Surgery, the American College of Forensic Examiners, and the International Network on Personal Meaning.

Early in his career, Maddi (1968) published a ground-breaking textbook: "*Personality Theories: A Comparative Analysis*." This book, which has been translated into several foreign languages and is still in print (in its 6th edition) has influenced several generations of psychology students and teachers, and has had a major impact on the field of personality psychology. The text takes a vigorous approach to evaluating the scientific merit of various personality theories, examining empirical support, and applying careful logical and conceptual analysis. From this has emerged his meta-theory of personality that has had a large effect on the expression of personality positions, and has identified key issues that need to be resolved through more precise theorizing and research. Essentially, he argues that there are three models of personality theorizing (conflict, fulfillment, and consistency), each with two subtypes. And, there are conceptual issues separating the three models, with empirical resolution of the issues being essential to progress.

As to his own personality theorizing, research, consulting, teaching, and counseling, Maddi started with the importance of the need for variety as an influence on curiosity and creativity (e.g. Maddi, 1965). As his career progressed, he drew on and elaborated existential psychology to further develop his theoretical and empirical approach concerning life's stressful nature, and how the pattern of attitudes and strategies he called hardiness can help in turning this from a potential disaster into a growth opportunity instead (e.g. Maddi, 1978, 1986, 2002). This work has been well received all around the world.

Maddi's current emphasis is research, assessment, and training of hardiness. This work began with a 12-year natural experiment at Illinois Bell Telephone (IBT) in Chicago. In this project, 450 managers were tested every year from 1975 through 1987 on a range of personality, health, and performance measures. Six years into the design, the anticipated federal deregulation of the telephone industry took place, and is still regarded as a major stressful upheaval. In the wake of this reorganization, two-thirds of the sample deteriorated in performance and health, whereas the other third showed resilience in not only surviving, but also thriving. The analysis of data collected before the upheaval showed that the resilient third had all along been stronger than the others in hardiness. Many papers and a book (Maddi & Kobasa, 1984) emerged from this seminal study.

Since the IBT project, hundreds of research studies on hardiness have been done by Maddi, his students, and others in this country and abroad. Hardiness has emerged as a pattern of attitudes and strategies that, together, help one to turn stressful circumstances from potential disasters into growth opportunities instead (Maddi, 2002). In this, the hardiness attitudes are the three Cs of commitment, control, and challenge. Strength in the commitment belief involves staying involved no matter how bad things get. Strength in the control belief emphasizes continually trying to influence outcomes rather than giving up. And, strength in the challenge belief indicates belief that life is by its nature stressful, and that this provokes trying to learn how to improve things. Together, these 3Cs provide the courage and motivation to do the hard work involved in learning how to grow from stresses. This hard work requires problem-solving (rather than avoidance) coping, socially supportive (rather than conflictful) interactions, and beneficial (rather than over-indulgent) self-care. Hardiness has been found to enhance performance and health, and protect against undermining negative emotions, in a large variety of stressful circumstances, such as

immigration, military and work deployment abroad, training in demanding jobs, and even college functioning (Maddi & Khoshaba, 2005).

In addition, hardiness assessment and training programs have been developed and validated. Assessment of the hardy attitudes, hardy strategies, stressfulness, and relevant emotionality is now available on an internet website: www.HardinessInstitute.com. Taking the assessment test produces a comprehensive report concerning hardiness characteristics and stress resilience levels. The hardiness training procedure involves doing exercises that will enhance the hardy attitudes and hardy strategies. In particular, this approach provides the trainee with the existential courage, motivation, and strategies to enhance performance and health by turning stressful circumstances from potential disasters into growth opportunities. The training is guided by a technologically advanced workbook, which is widely used and has been translated into several foreign languages (Khoshaba & Maddi, 2004). There is growing evidence showing that hardy training facilitates performance and health (e.g. Maddi, Harvey, Khoshaba, Fazel, & Resurreccion, 2009).

Over the years, Maddi has received many honors and awards. Among them are (1) being President of APA Divisions 1 and 10, (2) being a Fulbright Scholar in Brazil, (3) citation by the California Psychological Association as a major influence in its members' development, (4) inclusion among the 630 memorable psychologists and psychiatrists in R. J. Corsini's *Encyclopedia of Psychology*, (5) Distinguished Wellness Lectureship by University of California and HealthNet, (6) Diplomate, American Board of Forensic Examiners, (7) RHR International Award for outstanding contributions to positive psychology, (8) hardiness featured on the APA website, (9) Henry A. Murray Award by APA Division of Personality and Social Psychology, (10) Disabilities Services Center Faculty Recognition Award, University of California, Irvine, and (11) the American Psychological Foundation's 2012 Gold Medal Award for Lifetime Contributions to Psychology in the Public Interest.

Julie K. Norem

Sabrina Zirkel

Santa Clara University

Julie K. Norem, Margaret Hamm Professor of Psychology at Wellesley College, was involved in the early development of the concept of defensive pessimism while she was in graduate school. Since then, she has been a leading researcher of and writer on the concept of defensive pessimism specifically, as well as a proponent of multifaceted and integrative approaches to understanding individual differences in goal pursuit and personality more generally (e.g. Norem, 2010). She attended the University of Chicago on a writing scholarship, and graduated with honors as a Behavioral Sciences major in 1982. She received her doctorate from the University of Michigan-Ann Arbor in 1987. Norem was an assistant professor at Northeastern University in Boston, MA, and then moved to Wellesley College in fall of 1992. Her publications include empirical research, theoretical papers, commentary, review chapters, an edited volume, and her 2001 book, *The Positive Power of Negative Thinking*. Her work has frequently been featured in the national and international media, including the *New York Times, The Washington Post, The Globe & Mail*, *The Atlantic*, *Buenivida, The Huffington Post*, National Public Radio, and local and national news programs.

She is also one of a handful of researchers engaged in public critique and discussion of the Positive Psychology (0389) movement as a cultural phenomenon. She has done extensive professional service, including stints as associate editor of *Journal for Research in Personality* and *Personality and Social Psychology Bulletin*, and as member-at-large for both the Society for Personality and Social Psychology and the Association for Research in Personality. She was elected President of the Association for Research in Personality in 2006, and joined the board of the Foundation for Personality and Social Psychology in 2015.

At the University of Michigan in the mid-1980s, several graduate students began working with advisor Nancy Cantor (0300) on the concept of defensive pessimism, which Cantor had been discussing with Darren Lehman, Caroline Showers, and Aaron Brower, among others. Defensive pessimism is a strategy that anxious people (0221) may use to manage their anxiety and prevent it from interfering with progress toward their goals. The strategy involves two components: lowering expectations (i.e. being pessimistic), and then thinking through all the

negative possible things that might happen. When anxious people use defensive pessimism, their focus shifts from thinking about how anxious they feel to thinking about how they might prevent the disasters they imagine. Over 30 years of research have shown that defensive pessimism is an effective strategy for those who are anxious; anxious individuals who use defensive pessimism typically perform better and feel better than anxious individuals who use other strategies. Moreover, if defensive pessimists try to be more optimistic or more cheerful, their performance typically suffers (0272) (see Norem, 2008, 2014, for reviews)

Norem's earliest study of defensive pessimism was inspired by discussion in social psychology of self-esteem protection strategies described as "illusory" and focused on overly optimistic self-evaluations and other positively biased cognitive processes (0234). There was growing consensus among social psychologists – expressed most comprehensively and influentially in Taylor & Brown (1988) – that these positive biases were ubiquitous (characteristic of all non-depressed individuals) and fundamental to mental health. Both casual observation and more systematic review of descriptions of how different successful individuals prepared for performance situations, however, suggested that there might be important individual differences among those who were non-depressed, mentally healthy and highly functioning. Norem and Cantor (1986) showed that defensive pessimists did not engage in the kinds of positive biases other researchers had identified (e.g. claiming more control over successful performance relative to less successful performance), and later research showed that the lack of optimism and positive thinking characteristic of defensive pessimists did not put them at risk for depression (e.g. Showers & Ruben, 1990).

Several of Norem's later studies were based on the idea that one way to understand how a strategy like defensive pessimism works is to design experimental manipulations that interfere with parts of that strategy, and then observe their effects on relevant outcomes (0104). Thus, in a series of studies using different subject populations, tasks and manipulations, Norem and her colleagues were able to show that interfering with the negative expectations, the negative mood or the negative thinking of defensive pessimists leads to poorer performance (e.g. Norem & Illingworth, 1993). Defensive pessimists perform better and feel better when they use their preferred strategy. Those studies and others also show that individuals who use more optimistic strategies show performance decrements in some situations too: optimism does not confer invulnerability to context. Both those using optimistic strategies and those using defensive pessimism experience their best outcomes in contexts and situations that allow for or encourage their preferred strategies.

Norem's approach to the study of defensive pessimism has been at odds with several popular theoretical and research perspectives over the years. Her focus on individual differences in the paths that led to well-being has contrasted with the emphasis on positive thinking and optimism that were important foundations for the early growth of Positive Psychology. That focus is also generally incongruent with approaches to goal pursuit that identify effective vs. ineffective strategies, without consideration of the extent to which strategies are integrated with other aspects of personality, relevant to goals that may be specific to individuals, and varying in effectiveness depending on the context of goal pursuit.

Her insistence on the importance of social cognitive units of personality further contrasts with the dominance of trait approaches, particularly the Five Factor Model and Big Five perspectives, in personality psychology (Cantor, Zirkel, & Norem, 1993; Norem, 2010). Research on defensive pessimism reveals some of the limits to an exclusive focus on broad

traits; broad traits do not show differences between anxious individuals who use defensive pessimism and anxious individuals who do not, nor do trait approaches provide theoretical process descriptions that can account for the performance and other outcomes differences demonstrated by research on defensive pessimism.

Exploring the costs and benefits of different strategies as a function of who uses them in what contexts has led Norem to consider ways in which cultural sensibilities influence our assumptions about "good" strategies. The growth of culturally informed research in psychology felicitously coincided with, informed, and has been influenced by Norem's work on defensive pessimism. Several researchers from China, Korea, Japan, Singapore and other countries have built on work by Norem and Chang (2001) to show that the consequences of defensive pessimism and other strategies are influenced by cultural context: a 2008 review of 30 studies of defensive pessimism done by researchers in China is just one example of the influence Norem's work has had on psychology internationally (Su & Zhang, 2008). Ample evidence from multiple sources and contexts demonstrates that the American emphasis on optimistic strategies is not universal, and illustrates the ways in which the advantages of defensive pessimism may be augmented in family and cultural contexts that place more value on personal modesty and moderation than is typical in the United States.

Norem's influence in personality and social psychology stems from her research on defensive pessimism, her advocacy for integrative, contextually sensitive approaches to the study of personality and individual differences, and her service across a variety of roles. Norem has highlighted how simplistic models of personality – be they focused on individual traits or on emphasizing the positive outcomes of positive thinking – obfuscate rather than reveal much of what is interesting about individual personality.

Robert J. Plomin

James Kean

Swinburne University of Technology

Background

Robert J. Plomin was born February 20, 1948 in Chicago, Illinois. At age 10, Plomin discovered an illustrated textbook on evolution at the library and decided to borrow it and show it to his class at school. Owing to the quality of the teaching, Plomin and his sister were enrolled in a Catholic school over the local public school, despite not being religious. Although this school had a significant impact on his subsequent education, when a young Robert presented the book on evolution to his class, he was promptly suspended. Plomin attributes this moment in his life to his current atheism. Despite this, his exemplary scholastic record provided him with direct entry into high school (DePaul Academy) and further still to the university (DePaul University) both on fully paid scholarships. At a young age, Plomin became the assistant to the research director at an educational association. During his time at DePaul University in Chicago Plomin studied philosophy, but due to the enigmatic nature of philosophy, Plomin became dissatisfied and looked for topics that provided tangible answers. He soon transitioned into psychology, completing his BA in Psychology in 1970. He developed his love of behavioral genetics at the University of Texas during his PhD under the tutelage of renowned personality psychologist Professor Emeritus Arnold Buss.

Plomin completed his PhD in 1974, publishing a book a year later with Professor Buss on the temperament theory of personality providing evidence from evolution and genetics. This work spawned two measures of temperament: *the Colorado Child Temperament Inventory* and the *EAS (emotionality, adaptability sociability) Survey for Children*. In 1974, Plomin accepted a position at the University of Boulder in Colorado within the Institute for Behavioral Genetics and the Department of Psychology. During his time at Boulder, Plomin produced over 40 research publications investigating behavioral genetics, intelligence, and behavior as well as beginning his integral work into the gene–environment interactions of twin studies. It was at Boulder that Plomin worked with colleagues Gerald McClearn and John DeFries, on a genetics textbook that was published in 1975, and continues today in now its seventh edition – *Behavioral Genetics: A Primer*. The same year saw Plomin and

DeFries begin the Colorado Adoption Project (CAP) following both adopted and non-adopted children, which continues to monitor participants today. In 1982, Plomin was made professor at Boulder.

In 1984, Plomin moved to the Center for Advanced Study in the Behavioral Sciences in Palo Alto, then to Pennsylvania State University in 1986 to join the Department of Human Development and Family Studies. It was here he created the Center for Developmental and Health Genetics, an interdisciplinary center with fellow behavioral geneticist Professor Gerald McClearn. During this time, Robert married Judith Dunn, a British psychologist and academic. Plomin, then a Medical Research Council (MRC) Research Professor, and Dunn moved to England to the Institute of Psychiatry, Psychology, and Neuroscience within King's College, London where they established the Social Genetic and Developmental Psychiatry (SGDP) center with Sir Michael Rutter, professor of Child Psychiatry. Then in 1995, Plomin initiated what would become one of the world's largest longitudinal twin study in the world, the Twins Early Development Study (TEDS). The sample in TEDS includes over 10,000 pairs of twins between 1994 and 1996 who have been followed up for 25 years.

Major Contribution – The Twins Early Development Study (TEDS) and Behavioral Genetics

Early in his career, Robert Plomin's main interest was to understand how twins changed over their lifetime within the same family unit and when they were adopted. The TEDS recruited 15,000 pairs of identical and non-identical twins with 13,000 remaining in the study. The primary emphasis of the research is to illustrate why people differ in terms of their cognitive, behavioral and learning abilities. This research has demonstrated the importance of genetic factors in the mediation of the environment at the individual level. The field of behavioral genetics has grown exponentially over the last 50 years, with 20,000 publications occurring between 2010 and 2014 alone. The primary outcomes for the study are to understand the genetic links to cognitive abilities and disabilities and to what extent the individual's environment influences these genetic expressions; what factors contribute to the stability or change of these abilities and how these influence other abilities the individual may have; and finally, to identify the specific genes involved in these similarities and differences looking at genetic mutations (single nucleotide polymorphisms; SNPs) and any associations they may have to abilities or disabilities.

In 2016, Plomin and colleagues published the 10 most replicated findings from the study of behavioral genetics. Among these, Plomin states that all psychological traits demonstrate significant genetic influence and replication. The finding outlines that there has yet to be a "single adequately powered study reporting nonsignificant heritability." Additionally, although traits are highly heritable, they are by no means constant. That is, although a specific trait may have high heritability that does not mean it will necessarily present in every individual of that genetic line. In another replication, Plomin and colleagues report that traits must be the result of many genes that produce small effects. This replicated finding makes understanding inherited traits significantly difficult due to the fact that so many genetic variants are at play. Personality traits have been shown to be mediated genetically, that is, whenever two behavioral traits show a phenotypic correlation, the genetic contribution is significant. One unusual finding is that the heritability for intelligence increases throughout development. That is, as a

person ages, more genetic influences begin to take shape and therefore have greater influence. This is a unique finding as this does not occur with other traits. Plomin goes on to note that environmental measures and psychological traits are significantly mediated by genetics and that most environmental experiences for children of the same family will not produce the same effect for each child. Finally, Plomin describes that people who may have inherited the genetic code for a disorder would be at a genetic extreme, should they present with and be diagnosed with that disorder. Others may inherit the same genes, but not present with a diagnosis.

Other Notable Works

Following the publication of the book *The Bell Curve*, Plomin was one of 52 signatories invited to sign off on issues related to intelligence research in an editorial for the *Wall Street Journal* in 1994.

Acknowledgments and Awards

In a review of the second edition of Plomin, DeFries, and McClearn's book *Behavioral Genetics: A Primer*, Professor Hans Eysenck compliments the updated text's ability to guide the reader through the biological and statistical concepts as well as providing insights into genes, chromosomes, chromosomal abnormalities, and the mechanisms underlying heredity and behavior. Although his review praises the work, he criticizes the lack of information in the areas of criminal behavior and Big 5 personality traits, that he feels required greater dedication. Despite this, the book impressed the eminent professor, who wrote "…these and other criticisms cannot dispute the value of this book as the best available introduction to behavioral genetics."

   In 2002, the Behavior Genetics Association awarded Plomin the Dobzhansky Memorial Award for a Lifetime of Outstanding Scholarship in Behavior Genetics. He was awarded the William James Fellow Award by the Association for Psychological Science in 2004. In 2005, he was elected a Fellow of the British Academy (FBA), the United Kingdom's national academy for humanities and social sciences. In 2011, he received the Lifetime Achievement Award of the International Society for Intelligence Research. In 2017, Plomin received the APA Award for Distinguished Scientific Contributions. He has been president of the Behavior Genetics Association and is ranked among the 100 most eminent psychologists in the history of science.

Conclusion: Personality and Individual Differences

Robert Plomin's ongoing work with behavioral genetics is the largest contribution to the study of genetic inheritance in personality to date. The consistent findings from investigations into the area have established Plomin's behavioral genetics research as one of the largest evidence-based personality concepts in psychology. The TEDS longitudinal study continues to run after 25 years, providing vast quantities of data and critical insight into the field of personality and individual differences.

Julian B. Rotter

Bernardo J. Carducci

Indiana University Southeast

Julian B. Rotter was born in 1916 in Brooklyn, New York. During his youth, he spent a considerable amount of time in the Avenue J Library in Brooklyn, demonstrating a particular fondness for fiction. During his junior year in high school, while searching the library stacks for something new to read, he came across some books by Freud and Adler (Rotter, 1982, 1993). He became so engrossed with his newfound interest in psychoanalytical thought that by his senior year, he was interpreting the dreams of his high school friends. As a senior in high school, he wrote a thesis titled "Why We Make Mistakes" and dreamed of having a career in psychology.

Rotter pursued psychology during his undergraduate years at Brooklyn College, but he took it only as an elective. Because the climate of the Great Depression offered few career opportunities in psychology and the college did not have a formal psychology department, he could not major in psychology. Instead, Rotter selected chemistry, a more practical major that promised a greater likelihood of a job after college. Even so, he took more courses in psychology than chemistry. One of Rotter's teachers was Solomon Ash, whose classic research on conformity and group influence would eventually make him an influential social psychologist. In addition to taking courses from Ash, Rotter had the opportunity to meet Alfred Adler. In his junior year at Brooklyn College, Rotter learned that Adler was teaching at the Long Island College of Medicine, where he was a professor of medical psychology. Rotter attended some of Adler's lectures and several of his clinical demonstrations. While still in college, Rotter got to know Adler personally. He attended monthly meetings of the Society of Individual Psychology at Adler's home, where Adler spoke on individual psychology. In response to Adler's passionate lectures, the young Rotter became even more convinced that his future would be in psychology. Although Adler's influence on Rotter had begun when he read Adler's books during high school, it did not end with these lectures. Some 40 years later, Rotter stated that Adler had been "a strong influence on my thinking. I was and continue to be impressed by his insights into human nature" (Rotter, 1982, p. 1).

Rotter graduated from Brooklyn College in 1937. Inspired by Adler and encouraged by two of his undergraduate professors, Rotter decided to pursue graduate study in psychology at the University of Iowa, in Iowa City, Iowa. He arrived at the University of Iowa with enough money to last a few weeks. However, the chair of the psychology department was able to obtain a research assistantship for Rotter, giving him enough money to survive. At the University of Iowa, he took a seminar in social psychology taught by the noted and very influential social psychologist Kurt Lewin. Lewin was famous for his work on how people use personal and environmental factors to determine their perceptions and reactions to the world around them. The critical importance of personal and situational variables in the interpretation of events and as determinants of action was to become a central feature of Rotter's own theory of personality.

In 1938, Rotter received his MA and moved to Massachusetts to attend Worcester State Hospital, at that time a major training and research center in clinical psychology. At Worcester, he participated in one of the first ever internships in clinical psychology; he also met Clara Barnes, his future wife. Hoping to be one of the first clinical psychologists, Rotter left Worcester to attend Indiana University, where in 1941 he received his PhD in clinical psychology; he was married to Clara that same year.

After receiving his PhD, Rotter wanted an academic position. But he soon discovered that the warnings he had been given since his days at Brooklyn College about Jews not being able to obtain academic jobs, regardless of their credentials, were now becoming reality. Rotter accepted a position at Norwich State Hospital as a clinical psychologist. At Norwich, his responsibilities included the training of interns and assistants from the University of Connecticut and Wesleyan University. In 1942, Rotter was drafted into the army. He spent the next three years as a military psychologist, where he served as a consultant, helped with officer candidate selection, and developed a method for reducing the incidence of absence without leave (AWOL).

After his military service, Rotter returned briefly to Norwich State Hospital. But he soon discovered that the shortage of clinical psychologists after World War II created a need for his services sufficient to overcome the anti-Semitism that had once prevented him from obtaining an academic position. Rotter had many universities from which to select. He soon accepted a position at Ohio State University in the clinical psychology program, from which Carl Rogers had recently departed. Like Rogers before him, Rotter combined his emphasis on scientific research within the clinical setting to help build a clinical psychology program rated among the best in the country. Rotter became the director of the clinical psychology program in 1951.

During his stay at Ohio State University, Rotter formulated and, along with a group of outstanding graduate students, tested and developed the basic framework of his social learning theory. The culmination of this work was his classic textbook titled *Social Learning and Clinical Psychology* (Rotter, 1954). In addition, it was during this period that he began a program of research investigating his most famous contribution to personality psychology – the construction and validation of the Internal-External Control of Reinforcement Scale (I-E Scale) (Rotter, 1966). The I-E Scale is designed to measure the extent to which an individual holds the generalized expectancy that reinforcements in life are controlled by internal factors (e.g. what you do) or external factors (e.g. luck, fate, or the power of others). People who tend to express a belief

reflecting a generalized expectancy of an internal locus of control are referred to as "internals," while those who express an external locus of control are referred to as "externals" (Rotter, 1966, 1975).

Although he was very happy and extremely productive at Ohio State, Rotter was quite disturbed by the political climate created in the Midwest by the Communist-baiting Senator Joe McCarthy. As a result, Rotter left Ohio State in 1963 and moved to the University of Connecticut, where he continued to refine his theory, conduct research, supervise the training of clinical psychology graduate students, and see clients in his private practice as a clinical psychologist. A significant characteristic of Rotter's distinguished career had been his emphasis on training clinical psychologists to be both researchers and practicing clinicians. This is a philosophy Rotter maintained during his 50 years as a clinical psychologist.

Rotter retired in 1987 from his faculty position at the University of Connecticut. But true to his lifelong philosophy as a scientist-practitioner, Rotter continued to teach and supervise the research and clinical training of graduate students at the University of Connecticut. In addition, throughout his career, Rotter had been active in many professional associations, serving as president of the Eastern Psychological Association, as well as president of Division 8: Personality and Social Psychology and Division 12: Clinical Psychology of the American Psychological Association (APA). He also served as a member of the Educational and Training Board of the APA, the APA Council, and the United States Public Health Service Training Committee. In recognition of his many significant contributions throughout his lifetime of work, Rotter received the prestigious APA Distinguished Scientific Contribution Award in 1988 and, in the following year, the Distinguished Contribution to Clinical Training Award from the Council of University Directors of Clinical Psychology.

In addition to his many important contributions to the study of personality and clinical psychology noted previously, some of his other significant publications include *Clinical Psychology* (Rotter, 1971), *The Development and Application of Social Learning Theory: Selected Papers* (Rotter 1982), *Applications of a Social Learning Theory of Personality* (Rotter, Chance, & Phares, 1972), and *Personality* (Rotter & Hochreich, 1975). In addition to the I-E Scale, Rotter's contributions to the development of other measures of personality include the Rotter Incomplete Sentences Blank Manual (Rotter & Rafferty, 1950) and the Interpersonal Trust Scale (Rotter, 1967).

On January 6, 2014, Rotter died at the age of 97 at his home in Mansfield, Connecticut. More information on Rotter's life can be found in a chapter he wrote titled "Expectancies," which appears in *The History of Clinical Psychology in Autobiography* (Walker, 1993).

Mark Savickas

Annamaria Di Fabio[1] and Jacobus Gideon Maree[2]

[1] *University of Florence, Italy*
[2] *University of Pretoria, Italy*

Savickas has established himself as the global leader in research in the field of Career Counseling. His research has been published in every major international journal in the field of Counseling Psychology, he is by far the most prolific and significant author in his field and he has published a vast array of ground-breaking scholarly contributions in all the leading international journals in the field of Counseling Psychology. His stature in the field of Counseling Psychology is evidenced by his election to the office of President, Counseling Psychology Division, International Association for Applied Psychology (IAAP) but also to multiple other positions.

Our opening outline sets the framework for some of Savickas' more specific research accomplishments, which will now be delineated.

Mark L. Savickas is professor of family and community medicine and chair emeritus of the Behavioral Sciences Department at the Northeast Ohio Medical College in the United States. He earned his doctorate from Kent State University in 1975, before licensure requirements dictated the curriculum. Based at Kent State University, he was able to visit and study with leaders of vocational psychology such as Donald E. Super, John O. Crites, and John L. Holland rather than just reading their work. Super and Holland, who worked in different paradigms, sponsored his dissertation research under the direction of Glenn A. Saltzman. That study investigated the hypothesis that the developmental construct of career choice readiness related highly to the personality construct of consistency. The project set Savickas on a career path in which integration of theories and convergence of constructs play a prominent role. He repeatedly researched the relation between the two dominant and most useful models of vocational behavior, namely, the differential psychology model of John L. Holland with the developmental psychology model of Donald E. Super. This research and reflection produced 10 authored or edited books (many of which are generally regarded as classics in the field), 40 book chapters, 100 articles, three psychometric inventories, and 175 papers at conferences.

Savickas has received the highest awards given by the Society for Counseling Psychology, the Society of Vocational Psychology, the European Society for Vocational Designing and Career Counseling, and the National Career Development Association. He is a fellow in the Association for Psychological Science, the American Counseling Association, the National Career Development Association, and the Clinical Psychology Division in the American Psychological Association. Savickas served three-year terms as a visiting professor in the Department of Organizational Behavior in the School of Business at Loughborough University, United Kingdom; visiting professor at the Vrije Universiteit Brussels (Belgium), and visiting professor in the Faculty of Education and Psychology at the University of Lisbon in Portugal. Moreover, he received honorary doctorates from the University of Lisbon (Portugal) and the University of Pretoria (South Africa). These awards testify to and celebrate his single-handed reshaping of the face of career psychology in our time (Maree, 2013, 2016, 2019).

Savickas has presented more than 500 lectures and workshops to professional groups in 16 countries. To share teaching materials such as tests and videos, he set up a website, Vocopher.com, as a collaboratory for faculty who teach vocational psychology. As an adjunct professor at Kent State University since 1975, he has taught career counseling to 5,000 students and sponsored the doctoral dissertations of 32 students. In addition, he has had teaching appointments in the Psychology Departments at Vrije University (Belgium) and the University of Lisbon (Portugal), in the Department of Organizational Behavior at Loughborough University (England), and the Department of Educational Psychology at the University of Pretoria (South Africa).

From 1991 to 1998, Savickas served as editor-in-chief of *Career Development Quarterly* and from 1999 to 2016 he served as editor-in-chief for the *Journal of Vocational Behavior*. During those years, he also served on 22 editorial boards for journals in 12 countries. He used these posts to further the careers of new professionals seeking to publish their first manuscripts as well as craft special issues to highlight problems and possibilities in vocational, industrial, and organizational psychology. He also leveraged his positions in professional organizations to foster the career development of new professionals and assistant professors. In 1987 he founded the Vocational Psychology and Career Intervention Special interest Group (SIG) in the Counseling Psychology Division (17) of the American Psychological Association, leading it for nine years until it became the Society for Vocational Psychology. Under his leadership from 1990 to 1995 that group sponsored seminars in Belgium, Canada, and Portugal.

Savickas served in 2003 as founding Vice-President for the Counseling Psychology Division (16) and from 2010 to 2014 served the Division as President. One of his presidential initiatives was try to reunite the two wings of vocational psychology, namely, researchers who study adolescent career development and researchers who study adult career development. As part of this effort, Kerr Inkson and Savickas (2012) edited the four-volume set entitled *Major Works in Career Studies* that contained 79 articles selected because of their exceptional impact and influence and written by members of the two groups.

During the first half of his career, Savickas studied individual differences in vocational behavior, always attempting to integrate Super's model of readiness with Holland's model of resemblance. He examined the convergence of career development variables to individual difference variables such as decidedness, interests, identity, and time perspective.

At midcareer, he took a major step by organizing with Robert W. Lent (1994), the first Vocational SIG conference on the topic of Convergence in Career Theories. Slowly, his own work shifted from integrating different theories to unifying the segments within one theory. His mentor Super had near the end of his career published a life-span, life space model with three major segments – individual differences, developmental tasks, and self-concept. Super hoped to someday integrate these segmental theories using a superordinate construct such as learning. Focusing on Super's goal of segment integration, Savickas eventually used the epistemology of social constructionism to craft an integration which he called career construction theory. A central part of that theory resulted from shifting focus on career maturity as an organismic variable that unfolded over time to career adaptability as a contextual variable responding to vocational development tasks, occupational transitions, and work traumas.

Following a suggestion by Super and Knasel, Savickas (1997) wrote an influential article (cited by 587 scholars) proposing the construct of career adaptability as an integrative construct for bridging theory segments. Inspired by McAdam's (1995) tripartite model of personality, Savickas reshaped the theory segments to describe vocational behavior from the three perspectives on the individual as object, subject, and project. Viewing vocational behavior from these three perspectives explains the interpretive and interpersonal process through which individuals construct themselves as actors, impose direction on their vocational behavior as agents, and make meaning of their careers as authors. To unify the three perspectives, he used the epistemology of social constructionism, thereby crafting the theory of career construction (cf., Savickas, 2005).

Within the theory of career construction, Savickas articulated a model of adaptation that coincided with its three perspectives. The model begins with the actor who shows some degree of readiness to adapt. Adaptivity or readiness denotes the personal characteristics of flexibility or willingness to meet transitions with fitting responses. However, adaptiveness is insufficient to support adapting behaviors; it must be accompanied by the agent's self-regulation resources to address the changing situation. Career construction theory refers to these psychosocial resources as adaptabilities with which to solve the unfamiliar, complex, and ill-defined problems presented by tasks, transitions, and traumas. Four key adaptabilities are concerned with the future, control of intentional vocational actions, curiosity about possible selves and occupational options, and confidence to deal with barriers. These adaptabilities condition the activities of adapting, that is, behavioral responses such as exploring, deciding, planning, and so on. The outcome of a cycle of adaptivity-adaptability-adapting is adaptation, operationally defined as success, satisfaction, and well-being (Maree, 2017, 2018).

There existed excellent measures to operationally define three parts of this model, but not for adaptability resources. Sponsored by Division 16, Savickas and his colleagues Maria Eduarda Duarte and Fred Leong organized a group of psychologists from 15 countries to meet at a series of international conferences to craft a psychometric measure of career adaptability. The *Career Adapt-Abilities Scale* (*CAAS*) was developed jointly by colleagues from across the globe and enabled international comparison yet also fit local contexts (cf., Leong & Walsh, 2012). The CAAS has been translated into 20 languages and is used extensively in research on vocational behavior and career development.

Together with Van Esbroeck from Vrijie University in Brussels, Savickas organized the life-design international research group with members from seven European countries. Working collaboratively, they produced an influential statement of life design as third paradigm for career intervention rooted in social constructionism (Savickas et al., 2009). This highly cited article has been translated into six languages. Savickas then published a book on life-design counseling (2011), an instructional manual for learning life-design counseling (2015), a client workbook (Savickas & Hartung, 2012), and demonstration DVDs (2009). Throughout these materials, he maintains the distinction between career construction as a theory of vocational behavior and life designing as a counseling discourse.

Savickas' scholarly efforts can best be described as pioneering; the Olympic gold medal standard in the field of career counseling. Savickas' article entitled "Career counseling in the postmodern era" (Savickas, 1993) (cited by 324 scholars) caused a shift in the tectonic plates of career counseling. It helped to change the course of career counseling and was followed by numerous other ground-breaking publications from his pen. In 2011, and again in 2019, Savickas brought together his insights and contributions in a single publication, entitled *Career counseling* (editions one and two) (Savickas, 2011, 2019), which constitutes a benchmark for everyone writing on the subject. Savickas' greatest achievement, though, is the fact that he has single-handedly liberated career counseling theorists and practitioners alike from the shackles imposed by an overly positivist approach in the twentieth century – an approach which left little room for consideration of issues such as subjectivity, personal growth, discovery and improving the sense of self during career construction.

This biography represents a very small token of the love and respect for Savickas as well as our gratitude to a very rare, special and once-in-a-lifetime maestro, who exemplifies the finest possible blend of genuine giftedness, love for others, and scholarliness. Savickas deserves the highest award and accolades the world can bestow upon him.

Dean Keith Simonton

Rodica Damian

University of Houston

Dean Keith Simonton, who received his PhD in Social Psychology from Harvard University, is a Distinguished Professor Emeritus at the University of California, Davis. His highly interdisciplinary research centers on the study of genius, creativity, leadership, and esthetics. Through his work, we are now better able to understand to what extent a myriad of factors contribute to greatness in the sciences, arts, and politics. When asked why he dedicated his work to the study of greatness, Simonton recounted a vivid childhood memory where his parents purchased a set of encyclopedias. He remembered browsing excitedly through the volumes and wondering how anyone got to be featured there. This early experience led to a life-long interest in understanding what sets apart people who display genius-level accomplishments. Decades later, Simonton wrote *Great Psychologists and Their Times* (2002a). This was the first compilation of research and theory meant to elucidate the factors that contribute to success as a psychologist. Because one of the best ways to honor a scientist's contributions is applying them, this biography will follow the structure of the above-mentioned book, and will draw inspiration from Simonton's research findings and methods to conduct a case study of his own accomplishments.

Output and Impact on the Field

One of Simonton's major contributions to the field was introducing a new perspective on creativity where the creative product was the ultimate criterion of whether the process or the person could be considered creative (Simonton, 2003). This perspective is highly advantageous because creativity can be measured "in vivo" by conducting naturalistic and behavioral observations, and thus, the creative process and person can be better understood in a real-world context (Simonton, 2004). To achieve this, Simonton has contributed significant methodological innovations to the field of historiometrics. Specifically, he devised a wide range of at-a-distance methods to extract measures of greatness and related factors from biographical and historical materials.

Following Simonton's theory, the mark of a great scientist is a high level of productivity, and one way to measure productivity in science is by counting publications (Simonton, 2004). As of January, 2020, Simonton had 574 scientific publications, which places him at the top of the productivity distribution of eminent psychologists, and ahead of prominent figures from the history of psychology, such as Wilhelm Wundt (503 publications), Sigmund Freud (330 publications), and William James (307 publications). Productivity is an important marker of scientific achievement because it is related to increased research quality and a higher impact on the field (Simonton, 1992). This idea holds in Simonton's case, where his productivity has clearly been accompanied by a high level of research quality and impact.

The first and simplest way to measure research quality and impact on the field is to count citations. So far, Simonton's work has accumulated 27,250 citations, with a single year maximum of 1,916 citations in 2014.

Another way to measure impact on the field is to look at the type of contribution. A study of eminent psychologists found that books represent superior contributions because they claim a disproportionately high number of citations, presumably because they have some integrative advantages over journal articles (Simonton, 1992). Simonton has published 14 books so far, several of which are among his most cited works, with more than 700 citations each. Furthermore, his works have been translated in eleven different languages, thus reflecting Simonton's international acclaim.

A third way to measure impact on the field is to evaluate a researcher's record of awards and achievements. Among his research awards are the William James Book Award, the Rudolf Arnheim Award for Outstanding Achievement in Psychology and the Arts, and the Henry A. Murray Award. Simonton has also received numerous teaching awards, among which is the Robert S. Daniel Award for Four Year College/University Teaching. Last but not least, he was elected president of three scientific societies (Division 1 of APA, Division 10 of APA, and the International Association of Empirical Esthetics) and fellow of 17 scientific societies.

A fourth way to measure impact on the field is to conduct a qualitative analysis of someone's research contributions. In addition to being internationally renowned as the modern proponent of the field of historiometrics, Simonton has made significant contributions in general psychology, personality psychology, developmental psychology, quantitative psychology, and cross-cultural psychology, and published in journals outside of psychology in fields such as political science, physics, biology, and music. His research shows both theoretical and methodological breadth. Regarding theoretical breadth, Simonton has drawn inspiration from Darwin's theories of natural and sexual selection, Tolstoy's "Zeitgeist" theory of leadership, and Kant's definition of genius. He developed several major theories of creativity, including the blind variation and selective retention theory of creativity (Simonton, 2011) and a combinatorial model of the creative process (Simonton, 1997). He also made major contributions to the fields of political leadership (Simonton, 1988), cross-cultural psychology (Simonton, 1975), and behavioral genetics (Simonton, 1999). Regarding methodological breadth, Simonton's work includes single-case studies either qualitative or quantitative, multiple-case inquiries using individual or aggregate data, thematic and computerized content analyses, Monte Carlo simulations, mathematical models, and laboratory experiments. Although Simonton's work shows great theoretical and methodological breadth, it is also highly coherent, centering on greatness and genius. Achieving such a fine balance between

breadth and depth is yet another mark of highly successful scientists (Simonton, 1992). Thus, we can conclude based on Simonton's total creative output and impact that he is indeed an eminent psychologist. But how has his creative output changed over the years?

Creative Output Over the Lifespan

Simonton has devoted a significant portion of his research to understanding the development of creativity over the lifespan. How does creative output change over time and what does that reveal about the creative process? Using biographical data, Simonton has examined the creative life cycles or career trajectories of writers, composers, scientists, and political leaders. In doing so, Simonton (1997) has developed a combinatorial model of the creative process, whereby creative output is a function of initial creative potential, ideation (i.e. the generation of ideational variation), elaboration (i.e. the conversion of these ideas into finished works), and time (i.e. how long one has operated in a certain career). This model can be expressed as the following equation:

$$p(t) = c\left(e^{-at} - e^{-bt}\right),$$

where $p(t)$ represents the publication rate as a function of time, $c = abm/(b-a)$, where m is the initial creative potential, a is the ideation rate, b is the elaboration rate, e is the exponential constant (2.718), and t is career age. This model has been shown to fit a large number of career trajectories across disciplines and it renders a curvilinear function, where the creative person peaks in their late 30s or early 40s (i.e. 10–20 years into their career), after which their creative productivity steadily declines (Simonton, 1997). This is a highly generative model because it permits the testing of numerous hypotheses regarding the typical age curve, contrasts across disciplines, or even specific case studies and their comparison with the nomothetic baseline. Thus, with the help of this model we may ask how Simonton's
Figure 1 Simonton's creative output over the lifespan. "Productivity" represents the total number of publications across a given career decade. "Career age" represents the number of years since Simonton's first publication.

own career trajectory fits with the nomothetic baseline. Figure 1 addresses this question. The solid line represents Simonton's actual creative productivity, split by four consecutive career decades. The dotted line represents the nomothetic prediction made by the model for a person of similar initial creative potential as Simonton. As seen, Simonton's career trajectory departs significantly from the baseline. Specifically, he shows no signs of slowing down as time goes on, his creative output in his fourth career decade being almost twice the predicted amount. To explain his incredible productivity and unusual career trajectory, we must investigate his personal characteristics and work style, thus shifting focus from the creative product and process to the creative person.

Personal Characteristics

Extensive research (Simonton, 2004) suggests that highly creative scientists are ambitious, show a strong interest in science, read voraciously early on, and are high in openness to experience showing a broad range of hobbies and activities. Simonton fits this profile perfectly. His highly ambitious disposition pushed him through life and helped him refuse to conform to people's expectations and break all norms (Simonton, 2002b). For instance, in high school, one counselor tried to discourage Simonton from signing up for college-preparatory courses because of his socio-economic background. Despite this, Simonton not only ended up pursuing college, but he also got a full scholarship based on his many awards received in high school for science projects. Later on, he pursued a doctoral degree at Harvard, where he also got a full scholarship from the National Science Foundation based on his scientific merit. Besides his early scientific activities, which ranged from physics and chemistry to biology and history, Simonton also read voraciously. One particular story stands out from Simonton's teen years, when he spent all his money from a job at a car wash to purchase the anthology *Great Books of the Western World* (Hutchins, 1952). Furthermore, Simonton pursued numerous and widely varied hobbies, ranging from playing guitar in rock groups, to making art, playing high school football, and writing poetry. His interests in art, music, and poetry can still be seen today in his research on Picasso's art, Beethoven's symphonies, and Shakespeare's sonnets.

Finally, Simonton's work style is characteristic of highly creative and successful scientists. When asked what the secret of his productivity was, he reported having a "network of enterprises" (i.e. working on multiple projects simultaneously). This work style presumes that a researcher pursues a variety of projects that are in various states of progress. The advantage is that one always has something to work on and one can switch the type of task or project when reaching a roadblock and thus make most efficient use of time. In addition, people who use this work style often benefit from cross-talk among the various projects by getting inspiration from one project to the other even when they seem unrelated. This work style might be responsible for Simonton's continued creativity and productivity throughout his career span.

Having evaluated the creative product, the creative process, and the creative person in this brief biography, using theory and methods borrowed from Simonton's work on highly successful scientists, the inevitable conclusion is that Simonton himself would make an excellent participant in his studies of great psychologists.

Marvin Zuckerman

James Kean

Swinburne University of Technology

Background

Marvin Zuckerman was born on March 21, 1928 in Chicago, Illinois to Eli and Sophia Zuckerman. He is best known for his work on the psychobiological basis for human personality, sensation seeking, sensory deprivation and mood state measurement. One of his earliest experiences with psychology was during his high school days, when Zuckerman taught himself graphology, the study of handwriting to infer someone's individual character. Using a textbook from the library for reference, he would acquire pieces of writing from family and friends and make character assessments of their personality. Zuckerman graduated high school at the age of 16 and began his college life at the University of Kentucky at the behest of his father despite his own desire to join the Navy. During his time at Kentucky, he was exposed to the works of Sigmund Freud and began to interpret the latent content of his own dreams. However, once he was 18, Zuckerman joined the peacetime army. Unfortunately (or not), this was short-lived and after a year at a garrison in Texas due to the war being declared over, he returned to college.

In 1949, Zuckerman received his Bachelor's degree from New York University with ambitions of becoming a writer through his studies in journalism. As he began his postgraduate studies, Zuckerman turned his attention to medicine with intentions to pursue psychiatry but was drawn to one of the first clinical psychology programs that NYU offered. During this time he worked as a psychology intern at Wayne County General Hospital (1951–1952), and after completing his PhD in clinical psychology, he worked as a clinical psychologist at Norwich State Hospital (1953–1954) and then at Larue D. Carter Memorial Hospital (1954–1956). In 1956, Zuckerman was offered the position of assistant professor of psychology and began a research associate position at the Institute for Psychiatric Research within the Indiana University Medical Center, where he studied anxiety and sensory deprivation. This work would lead him to the development of his general theory of sensation seeking and the psychobiological explanations for individual differences in its expression. In 1960, Zuckerman was given the role of assistant professor of psychology at Booklyn College and

then as an associate professor of psychology at Adelphi University. In 1963, Zuckerman became a research associate at the Albert Einstein Medical Center in Philadelphia within the Department of Endocrinology and Human Reproduction. Zuckerman then moved to the University of Delaware in 1969 as an associate professor, but it was not long before he was offered a professorship in psychology in 1971. He became the program director for training in clinical psychology in 1976. He became a research fellow at the Institute for Advanced Study in the Netherlands in 1987 and was finally awarded the status of professor emeritus in 1993.

Over the years, Zuckerman would often spend his sabbaticals in England liaising with prominent personality psychologists Hans Eysenck, Robert Plomin, and Jeffrey Gray. Through collaborative factor analysis, the group arrived at the conclusion that impulsivity and sensation seeking formed a reliable personality dimension. Zuckerman remained at the University of Delaware until 2002 when he retired at the age of 74. Despite retirement, Zuckerman holds an appointment as a research professor at the Jefferson Medical University in Philadelphia where he continues to collaborate on research. Marvin Zuckerman continues to write journal articles, book chapters, and revisions of his 1991 book *Psychobiology of Personality*. During his married years, Marvin Zuckerman had two children, Steven and April, both of whom are family therapists.

Major Contribution: Sensory Deprivation and the Theoretical Basis of Sensation Seeking

For 10 years, Marvin Zuckerman studied the effects of sensory deprivation (perceptual isolation) and its effects on visual and auditory perception. The investigations provide a psychobiological understanding of personality, citing visual and auditory hallucinations as key indicators for underlying neurological arousal. These National Institute of Mental Health (NIMH) funded research studies were supported by data from concurrent projects including West's (1962) sensory deprivation experiment reporting "the greater the level of arousal during reduced sensory input, the more vivid the hallucination." Zuckerman's *optimum level of arousal* hypothesis asserts that people with high levels of sensation seeking seek more stimulation to elevate their arousal to their individually ideal level. He reports that the reticular activating system (RAS), a network of neuronal fibers originating from the midbrain that project throughout the cerebral cortex and control arousal, requires greater stimulation in those who are sensation seeking. When this optimal level of arousal is not met, the individual may find the presenting experience unpleasant.

In 1964, following his work in sensory deprivation, Zuckerman created the *Sensation Seeking Scale* (*SSS*). It is made up of four subscales (comprising 10 items each) designed to measure how the psychological and biological mechanisms for personality interact. Using factor analysis, he defined the subscales within the scale as *Thrill and Adventure Seeking* (*TAS*), *Disinhibition* (*Dis*), *Experience Seeking* (*ES*), and *Boredom Susceptibility* (*BS*). Its current form (Form V; 1978) is the most widely used measure of sensation seeking to this day. A children's version was created in 1993 with varied subscales (*Thrill and Adventure Seeking*, *Drug and Alcohol Attitudes*, and *Social Disinhibition*) as was a shortened version of the scale (BSSS). This measure of a person's optimal arousal

level allowed greater insight into other distinct personality traits including neuroticism, antisocial behavior, and psychopathy.

Major Contribution: The Psychobiology of Personality (1979)

This book was written with a connectivist approach in an attempt to close the knowledge gap between psychologists and geneticists. Zuckerman comments that "Eysenck (1967) was an exemplar of the top-down approach and Gray (1982) is one for the bottom-up approach." And adds that he has written this and previous texts from the top-down approach. That is, describing the outward behavior and personality and relating it back to the underlying biological mechanisms. He remarks that phrenology (pseudoscientific correlations of skull shape and personality) set back the study of personality due to years of tenuously proposed psychobiological relationships. However, research into genetics and psychology prevailed and the synthesized field of study was eventually adopted by a number of prominent psychologists including Zuckerman. In the book, Zuckerman cites Plomin (1986), describing their investigation into what they called the three types of *genotype–environment correlation*. This is where a genetically inherited behavior is recognized and reinforced by the parents (*passive*), when the behavior of the child changes the environment the child is in (*evocative*), and where the child must seek out specific elements of the environment that match their genetic predisposition (*active*). Zuckerman dedicates much of the book to providing the evidence for these gene-environment correlations for each of the personality traits (and sub-traits) included in his alternative Big 5 personality questionnaire. His distinctive method of linking the psychology of personality to a biological mechanism has made his psychobiological personality theories essential reading for any practicing or prospective psychologists or psychiatrists.

Other Notable Works

Development of the Zuckerman Personality Questionnaire

Zuckerman developed what came to be known as *the alternative five model of personality*. It was created to replace the Five Factor Model of Personality, asserting that personality traits must demonstrate a rich biological foundation. Instead of the previously established factors of *Openness to experience*, *Conscientiousness*, *Extraversion*, *Agreeableness*, and *Neuroticism*, Zuckerman's original "Alternative Five" were *Neuroticism-anxiety*, *Aggression-hostility* vs *Social desirability*, *Impulsive sensation seeking*, *Sociability*, and *Activity*. Today this questionnaire is known as the *Zuckerman-Kuhlman Personality Questionnaire* (ZKPQ).

Acknowledgments and Awards

In 2004, a symposium on personality at the University of Delaware was held in recognition of Zuckerman's significant contribution to the field. In 2004, a book of essays was created by colleagues and experts in the field of personality in honor of his work in the field.

Conclusion: Personality and Individual Differences

Professor emeritus of psychology Marvin Zuckerman's contribution to the field of personality and the correlations to psychobiological mechanisms have demonstrated that sensation seeking is one of many core traits that can help explain human personality and individual differences. Sensation seeking is deemed to be independent of other major dimensions of personality. In a personality biography written by Zuckerman, he notes the particularly high heritability of the sensation seeking trait. He reports that the magnitude with which it is inherited means that it is not "… just a minor subtrait of personality, but one with a strong evolutionary-biological source." He goes on to comment that the biological basis of the trait is strongly associated with our human desire to explore new things in our environment. His work in the field of personality has allowed psychologists to gain a more complex picture of individual personality types at the behavioral and biological level.

Raymond B. Cattell

Gregory J. Boyle

University of Melbourne

Raymond B. Cattell, PhD, DSc, was born on March 20, 1905 in West Bromwich, a town in the West Midlands conurbation, England. He died on February 2, 1998 at his home in Honolulu, Hawaii, and is buried in Oahu in the Valley of the Temples. Cattell grew up in the coastal countryside of Devon, where he spent a great deal of time hiking, sailing, and exploring the sea coast and hills around Torquay (his first book documented these early adventures: *Under Sail through Red Devon*, 1937). Although Cattell's father was a self-taught engineer and inventor, no one in his family had attended university. However, Cattell's exceptional abilities, especially in the sciences, led him to his earning a scholarship first to the Torquay Boys' Grammar School (1915–1921), and then a county scholarship enabling him to complete a BSc degree (with first-class honors) in chemistry and physics at the University of London, which he finished in 1924, at only 19 years of age (Gillis, 2014).

Cattell was influenced by the tremendous intellectual and cultural upheaval in London after World War I, where he read and interacted with other young free thinkers, such as Bertrand Russell, George Bernard Shaw, H. G. Wells, and Aldous Huxley. In his hometown of Torquay, Cattell had seen with his own eyes the terrible human toll of World War I, as injured soldiers arrived on trains directly from the battlefields in France to the hospital near to his home. After much deep reflection, Cattell came to the conclusion that solutions to human problems might be found by applying the objective, rigorous tools of science to the new domain of psychology, and understanding more about personality and human nature. He was discouraged by what he found in the current psychology of the day, which was largely made up of experimental psychologists who studied limited physiological issues (e.g. Pavlov's classical conditioning studies), or philosophically - oriented theorists (such as Freud) who developed their own subjective theories based largely on their own clinical work with troubled, abnormal individuals.

In pursuing this goal, Cattell's study of the periodic table of chemical elements (first put forward by Medeleev in 1869) led him to the idea of similarly trying to discover and elucidate the underlying structures of human personality. He reasoned that human personality

must have underlying structural dimensions in the same way that the physical world has underlying elements such as hydrogen and oxygen, and that if these basic building blocks could be discovered and measured, they could be used to understand and predict a wide range of behaviors, such as creativity, leadership, altruism, or aggression.

Cattell was interested in the work of Charles Spearman who was, at that time, trying to develop the methods of factor analysis to discover the basic factors of human abilities. Cattell (1984) stated that, "On a cold and foggy London morning in 1924, I turned my back on the shining flasks and tubes of my well-equipped chemistry bench and walked over to Charles Spearman's laboratory to explore the promise of psychology." Thus, he enrolled as a doctoral candidate in psychology at King's College, London under the guidance of Francis Aveling (Child, 1998; Sheehy, 2004) – third President of the British Psychological Society (1926–1929). In 1932, while teaching at University College, Exeter, Cattell also obtained an MA degree in education from the University of London.

After receiving his PhD in 1929, and working for several years in non-research teaching and clinical positions, Cattell found that there was very little funding for research in England at that time. Thus, when, in 1936, he received an offer to work in a research laboratory at Columbia University under Edward Thorndike, he left his home country to move to the USA in order to follow his interest in pursuing research into human personality structure. Next, Cattell accepted the G. Stanley Hall Professorship at Clark University (Massachusetts), where he worked on developing objective measures of personality and intelligence (1938–1941). There, he clarified his theory of fluid versus crystallized intelligence, which he presented at the 1942 APA convention. While at Clark, Cattell was a recipient of an honorary Doctor of Science (DSc) degree from the University of London (1939). Subsequently, he was offered an academic post at Harvard University (1941–1945), where his thinking about personality was influenced by the stimulating environment of numerous creative personality psychologists, such as Henry Murray, Robert White and Gordon Allport. During World War II, Cattell worked as a civilian consultant to the Personnel Research Division, developing psychological tests to be used for the selection of officers.

In 1946, Cattell accepted the newly - created University of Illinois Distinguished Research Professorship, which allowed him to focus more on research. He was particularly interested in the University of Illinois because they were currently developing the first electronic mainframe computer (Illiac I), which would make it possible to carry out large-scale factor analyses (Cattell, 1984). Here, Cattell founded the Laboratory for Personality and Group Analysis and began a period of intense creativity and productivity. He invited gifted colleagues from around the world who also were excited about contributing to the new science of psychology. Together, they embarked on a comprehensive program of taxonomic research conducted over several decades (1946–1973), aimed at identifying and mapping the underlying dimensions of human personality structure. This expanded to include not only the mapping of the domain of normal personality, but also abnormal personality, cognitive abilities, motivation, vocational interests, and affect states. Cattell continued his research and writing for another five years in Colorado, followed by his appointment as an Honorary Professor at the University of Hawaii, commencing in 1978 at 73 years of age.

A description of this research can be found in several of Cattell's books such as: *The Description and Measurement of Personality* (1946), *Personality and Motivation Structure and Measurement* (1957), *Personality and Mood by Questionnaire* (1973). In these writings,

Cattell described a complex program of personality research that resulted in a comprehensive model of the development and organization of personality over the life span. Cattell's empirically - based model included multiple types of input variables that influence personality (family, culture, genetic, and physiological factors), as well as multiple types of outputs (such as behavioral changes, personality and motivation changes, etc.). Child (1998) noted that Cattell's "major concern was to map out an integrated theory of human intellectual, temperamental and motivational characteristics within the context of hereditary and environmental influences using multivariate methods of analysis." Cattell's books were widely read, and they influenced the design of personality research around the world. For example, Cattell's book published in 1961 (with Ivan Scheier) on anxiety and neuroticism has become the core of modern state-trait theory.

Cattell's scholarly output was enormous at his University of Illinois laboratory, producing more than 50 books, over 550 journal articles and book chapters, as well as constructing more than 30 sophisticated psychometric instruments. As Dennis Child (1998) stated, "His major concern was to map out an integrated theory of human intellectual, temperamental and motivational characteristics within the context of hereditary and environmental influences using multivariate methods of analysis." Based on the peer-reviewed journal literature alone, Cattell was ranked among the top 10 most highly cited psychologists of the twentieth century (see Haggbloom et al., 2002, Table 1). Cattell's lifelong theoretical and quantitative research was focused on the rigorous scientific discovery, elucidation and measurement of psychological constructs – an admirable pursuit fully deserving of the highest accolade. So significant were Cattell's empirical contributions, and so extensive was the network of international researchers and distinguished scholars who collaborated with him over the years, that this whole genre of psychological research is now referred to as the Cattellian School of Psychology.

Psychology has advanced significantly as a result of Cattell's scientifically - oriented endeavors, not only in personality theory, psychometrics, and test construction, but also from his innovative contributions to specific theories – for example, his creative conceptualization of the Data Box describing the various combinations of persons, tests, occasions, backgrounds, and observers; the distinction between surface (observed) and source (latent) traits used in factor analysis, path analysis, structural equation modeling, item response theory, latent growth modeling, multi-level modeling, as well as multidimensional scaling; the state-trait distinction ranging all the way from transitory emotional states, longer-acting mood states, dynamic motivation traits, to enduring (relatively stable) personality dispositions; the distinction between fluid (Gf) and crystallized (Gc) ability – now extended as the Cattell-Horn-Carroll (CHC) theory of intelligence (see Schneider & McGrew, 2012); structured personality-learning theory involving trait change over the lifespan; innovations in factor analytic methodology; multiple abstract variance analysis (MAVA); as well as the multivariate measurement of cognitive abilities (see Cattell, 1987).

Cattell made many advances in factor analytic and other scientific methods (Cattell, 1978). His research was augmented by the presence of a talented group of psychometricians at the University of Illinois at that time, including Ledyard Tucker, Lee Cronbach, Paul Horst, and Henry Kaiser. When Cattell began his scientific research, factor analysis was a new and still - developing quantitative technique. It was largely through Cattell's empirical work and that of his students and colleagues that factor analysis became perhaps

the most widely used multivariate statistical technique for the elucidation of human personality structure (Nesselroade, 2001). Cattell was responsible for several creative innovations in factor analytic methodology, including the Scree Test of latent roots to determine the number of factors to extract (Cattell, 1966), rotation algorithms including both the analytical Maxplane and topological *Rotoplot* programs (used to attain maximum simple structure solutions), as well as the *Procrustes* program to test the validity of a hypothesized factor structure – Confactor rotation (comparing separate rotational solutions), the Taxonome program (for locating types), factor pattern similarity and congruence coefficients, as well as Conspect reliability (see John Gillis' chapter entitled "Quixote or Columbus?" in Miller, 1988). Cattell also showed how the $\pm.10$ hyperplane count provided a quantitative index of the degree of simple structure achieved.

Cattell's substantial contributions to factor analytic methodology (Cattell, 1978) and multivariate experimental research (Nesselroade & Cattell, 1988) have significantly advanced psychological science, and have facilitated the development of structural equation modeling. While multidimensional measures of personality traits such as the Sixteen Personality Factor Questionnaire (16PF) and the Clinical Analysis Questionnaire (CAQ) were derived from a programmatic series of regular (single-occasion*)* R-factor analyses, Cattell also utilized the innovative P-technique factor analysis (factoring a single individual's responses over say 300-350 consecutive days of test administrations), as well as the dR-technique (differential R-factoring of change scores across different measurement occasions) enabling the discovery and elucidation of state and dynamic trait factors.

Despite his many contributions to factor analytic methodology, Cattell considered structured learning theory and the dynamic calculus for assessing interests and motivational drives to be among his greatest achievements (Cattell, 1984). Thus, Cattell adopted a total approach to his scientific research that was objective, analytical, and replicable. Indeed, Lee Cronbach (1984) at Stanford University judged that, "[Cattell's] thirty-year evolution of ... methodology fed on bold conjecture, self-criticism, unbridled imagination, rational comparison of models in the abstract, and responsiveness to the nasty surprises of data. The story epitomizes scientific effort at its best."

Together with his wife Karen, Cattell built a psychological test publishing company – the Institute for Personality and Ability Testing (IPAT) – which has produced many sophisticated psychological measurement instruments (the Performance Assessment Network (PAN) Indiana, USA is now the parent company). IPAT researchers have constructed a wide range of psychometric instruments such as the Sixteen Personality Factor Questionnaire (16PF), and its downward extensions – the High School Personality Questionnaire (HSPQ), and the Early School Personality Questionnaire (ESPQ); the Clinical Analysis Questionnaire (CAQ) – revised as the Psychological Evaluation Questionnaire (PEQ) – which measures both the 16PF normal personality factors as well as an additional 12 abnormal personality factors; the Objective-Analytic Battery (OAB) – which provides objective (T-data) tests of 10 major personality factors; the Motivation Analysis Test (MAT), which is an objective measure of 10 important dynamic motivational trait dimensions, and its downward extensions – the School Motivation Analysis Test (SMAT), and the Children's Motivational Analysis Test (CMAT); the Eight State Questionnaire (8SQ) – a self-report rating scale which measures eight clinically important emotional/mood states; the Comprehensive Ability Battery (CAB) – which

measures 20 primary ability factors; and the Culture-Fair Intelligence Test (CFIT) – which minimizes the role of language and cultural learning in measuring intellectual ability.

The 16PF questionnaire is the perhaps best known of the many Cattellian psychometric instruments. The 16PF is a self-report (Q-data) measure of 16 primary personality trait dimensions. When the intercorrelations of these primary traits were subjected to second-order factor analysis, Cattell found that the primary traits coalesced into at least five second-stratum personality dimensions preceding the currently popular "Big Five" and the associated Five Factor Model (FFM) that were derived from analyzing a restricted subset of only 20 of Cattell's original 36 personality trait clusters (see Cattell, 1995; Krug & Johns, 1986). Boyle (2008) reported that the putative "Big Five" account for no more than 57% of the normal trait variance, let alone the abnormal trait variance, resulting from the restricted sampling of trait variables, thereby suggesting the need for extraction of additional second-stratum personality dimensions. The primary factors (traits such as warmth, self-control, dominance) have been found to be more powerful in predicting actual behavior. The 16PF remains a highly cited self-report measure of trait constructs and has grown to be one of the most widely used measures of normal-range personality in the world. The 16PF questionnaire has been translated and adapted into many different languages and cultures and is widely used especially in the USA, the UK, Europe, Australia, Canada, South America, and some parts of Asia. The 16PF has been used to assist in individual and group counseling, career guidance, employment selection and coaching (including selection for critical occupations such as Antarctic expeditioners), clinical and counseling psychology, as well as for research.

Cattell made many contributions to the study of intelligence. Important was his attempt to construct a culture-free intelligence test. This led to the development of figural matrices tests that are widely used in contemporary studies of fluid abilities (Gf) today. Another significant contribution was the investment theory (Cattell, 1987). Thus, crystallized intelligence (Gc) is said to reflect acculturational learning whereby learning outcomes are organized in the culture to help convert intellectual capacities captured by Gf into a form of intelligence deemed useful within a particular society. These learning experiences are accompanied by systems of reward and punishment that enhance or exclude some classes of behavior from one's behavioral repertoire.

Cattell was proactively involved in promoting international research collaboration. For example, in 1960 he founded the Society for Multivariate Experimental Psychology (SMEP), and its flagship journal *Multivariate Behavioral Research*, and subsequently produced two editions of the *Handbook of Multivariate Experimental Psychology*. For many years, the American Educational Research Association (AERA) has honored an outstanding researcher with the Raymond. B. Cattell Award. Likewise, the Cattell Early Career Research Award is given annually by SMEP to a young researcher who has made an outstanding contribution to multivariate experimental psychology and shows promise of continued work of a very high quality.

Cattell received many academic accolades, awards, and honors, including the Darwin Fellowship in 1935; the Wenner-Gren Prize of the New York Academy of Sciences in 1950; elected American Psychological Association (APA) Fellow; elected President of the Society of Multivariate Experimental Psychology (SMEP) in 1961; recipient of the Wisdom Award of Honor, 1970; election to the British Psychological Society (BPS) roster of distinguished

foreign psychologists in 1981; recipient of the Educational Testing Service (ETS) Award for Distinguished Service to Measurement in 1982; recipient of the APA Award for Psychometrics in 1983; and the Festschrift in honor of Cattell's lifetime contributions to psychological research and practice in 1986 (Miller, 1988). As a mark of respect for Cattell's prodigious scientific achievements, in 2014, the Raymond B. Cattell Scholarship was established by the Department of Psychology at the University of Illinois. Finally, in 1997, the APA announced that Cattell (at age 92 years) was to receive psychology's most prestigious honor, the American Psychological Foundation Gold Medal Award for Life Achievement in Psychological Science.

However, despite Cattell's indisputable scientific contributions, with no fewer than seven past APA presidents recommending him for the Gold Medal Award, at the last moment the Award was withheld due to an overtly political attack from two hostile critics (see Boyle et al., 2016). Contrary to the asseverations of these critics, Cattell had clearly eschewed racism and fascism (Dreger & Berg, 1998). In an open letter to the APA, Cattell (1997) declared that, "I abhor racism and discrimination based on race. Any other belief would be antithetical to my life's work." John Gillis (Cattell's official biographer) demonstrated unequivocally that these detractors had seriously distorted Cattell's position by taking quotes out of context, inserting their own words between his quotes, and referencing outdated writings from the 1920s and 1930s thereby giving a seriously false and misleading impression (Gillis, 2007). According to Gorsuch (1998), "The charge of racism is 180 degrees off track. [Cattell] was the first one to challenge the racial bias in tests and to attempt to reduce that problem" (as early as 1940, he had already devised the Culture-Fair Intelligence Test). In 1984, Cattell had specifically cautioned that eugenics should be considered only in relation to individual differences (such as eliminating genetically inherited diseases), not racial differences, and that birth control should be entirely voluntary. In addition, Cattell had emphasized that each culture should follow "its own path to maximize its own values and goals without suppression from any other culture" (Gorsuch, 1998).

Regarding the unsolicited accusations that resulted in withholding Cattell's Gold Medal Award, in an independent analysis, Lotz (2008) concluded that, "Cattell was deliberately misquoted on many occasions and labeled as an academic racist. The views he developed in the 1930s were common among his contemporaries when beliefs in racial differences were widely held, and should not be distorted by judgment according to today's standards. General scientific observations should not be read as personal moral statements. He was particularly wronged during the 1990s by certain writers (William H. Tucker and Barry Mehler) who picked out certain references referring to Germany, Hitler or genocide and quoted them out of context" (p. 136). Cattell was frail and in rapidly deteriorating health at the time of the Gold Medal Award, and passed away before he was able to correct these serious misrepresentations. In a recent (2014) review, Revelle concluded that this "spoke more about the political correctness of the APA than it did about the beliefs of a very creative and productive scholar."

Cattell was a humanitarian. Not only was he a scientist with high ideals in the pursuit of truth, but he was also a kind and generous man who had good intentions (as exemplified by the lasting legacy of a school he left for the impoverished children of Cambodia facing poor or non-existent opportunities for even a basic education). Cattell was proactive in mentoring his students and in collaborating with researchers all around the world. He would discuss their research interests with them at length, and encouraged and facilitated

their projects. He also was well-known for giving helpful advice and support when they ran into career or personal obstacles.

Cattell had been described by Goldberg (1968) as psychology's "master strategist." Few other psychologists have had as much influence on contemporary scientific psychology as has Cattell. John Horn wrote in 1998 that, "Cattell's research has contributed immensely to the breadth and depth of modern scientific psychology, both directly and through the hundreds of colleagues and students around the world with whom he worked.... in his remarkable 70-year career, Raymond B. Cattell has made prodigious, landmark contributions to psychology, including factor analytic mapping of the domains of personality, motivation, and abilities; exploration of three different media of assessment; separation of fluid and crystallized intelligence; and numerous methodological innovations....[Cattell] must be considered among a very small handful of people... who have most influenced the shape of psychology as a science."

Regarding metrics (see Haggbloom et al., 2002), Hans Eysenck (1985) had previously reported that, "According to the Citation Index ...Of the two hundred and fifty most cited scientists, only three psychologists made the grade, namely, Sigmund Freud in the first place, then the reviewer [H.J. Eysenck], and then Cattell. Thus there is no question that Cattell has made a tremendous impression on psychology and science in general." Dreger and Berg (1998) concluded that there can be little doubt that, "Raymond B. Cattell was one of the half dozen greatest psychologists of the twentieth century."

Contributor Biographies

Adisa Ajamu is the director of the Center for Black Cultures, Resources, and Research in the Department of Student Life and Leadership at the University of California, Irvine. He is an active member of the Association of Black Psychologists and the Association for the Study of Classical African Civilizations (ASCAC) and the author of numerous scholarly essays, articles, book reviews, and book chapters on African and African American life and culture, including the co-author of *The Psychology of Blacks: Centering Our Perspectives in the African Consciousness* and *The Psychology of Blacks: An African Centered Perspective*.

Hope Alvizar is a marriage and family intern who provides mental health services for at-risk youth and their families. She received her master of science degree in psychology from California State Polytechnic University, Pomona.

Leigh A. Andrews is a first-year doctoral student at the University of Delaware working with Dr. Adele Hayes. He graduated *cum laude* from Bowdoin College in 2015 and worked for two years as a research coordinator in the Psychotherapy and Emotion Research Laboratory under Dr. Stefan G. Hofmann. He is interested in mechanisms of treatment in emotional disorders, especially in novel forms of treatment with a particular interest in studying how some transdiagnostic factors, such as negative affect, emotional reactivity, and coping strategies like suppression, interact with treatment mechanisms.

Vanessa Geissler is a recent graduate of Antioch University Seattle and currently with the Washington State Department of Corrections. Her research interests include biracial identity, body image, and addiction studies. Her dissertation research explored the phenomenological experience of biracial woman and body image.

Patricia Arredondo is internationally known for her scholarly publications on multicultural competencies and guidelines for training, research, and practice, immigrants' mental

health and identity development, Latina/o psychology, women's leadership models, and organizational diversity strategies. Two of her major books are *Culturally Responsive Situational Counseling with Latinos* and *Successful Diversity Management Initiatives: A Blueprint for Planning and Implementation*. Dr. Arredondo holds fellow status with the American Counseling and American Psychological Associations. She is the founding president of the National Latina/o Psychological Association. Dr. Arredondo holds a doctoral

degree in counseling psychology from Boston University and is president of the Arredondo Advisory Group based in Phoenix, Arizona.

Neal M. Ashkanasy is professor of management at the University of Queensland, Australia with research interests in ethical behavior, leadership, culture, and emotions. He is a past editor-in-chief of the *Journal of Organizational Behavior*. Professor Ashkanasy is a fellow of the Society for Industrial and Organizational Psychology.

Arnold B. Bakker is professor of work and organizational psychology at Erasmus University Rotterdam, the Netherlands. He is also adjunct professor at Lingnan University, Hong Kong, and distinguished visiting professor at the University of Johannesburg, South Africa. Bakker is past president of the European Association of Work and Organizational Psychology. He is particularly interested in positive organizational behavior and happiness economics, including work engagement, happiness, JD-R theory, job crafting, creativity, and job performance. Bakker publishes regularly in the main journals in the field, including the *Journal of Organizational Behavior* and the *Journal of Vocational Behavior*. He is editor *of Current Issues in Work and Organizational Psychology* (Psychology Press). More information can be found at www.arnoldbakker.com or www.profarnoldbakker.com. Email: bakker@fsw.eur.nl.

Matthew T. Ballew, MA, is a PhD candidate in social psychology at Claremont Graduate University. His research interests focus on the psychological processes that facilitate prosocial and pro-environmental action. He also has research interests in the impact of natural environments (e.g. green spaces, parks) on individual and community health and wellness.

Lori A. Barker (PhD, UCLA, 1991) is a professor of psychology at California State Polytechnic University, Pomona. Dr. Barker is also a licensed clinical psychologist and founder of the Center for Individual, Family, and Community Wellness. Her main interest is in the impact of culture on behavior, cognition, and affect. She is co-author of *Multicultural Psychology: Understanding Our Diverse Communities* (4th edition, Oxford University Press), and editor of *Obama on Our Minds: The Impact of Obama on the Psyche of America* (2016, Oxford University Press). She regularly gives presentations and training sessions on culture and diversity at universities and community-based organizations.

Jennifer Barney is a doctoral student at Utah State University. Her research focuses on the evaluation of acceptance-based behavioral treatment approaches.

Arlin James Benjamin, Jr. earned his PhD in social psychology from the University of Missouri–Columbia in 2000. He is currently an associate professor in the Department of Behavioral Sciences at the University of Arkansas–Fort Smith. His primary research interests include in the study the effects of aggression-related situational cues (e.g. violent video games, weapon images) on aggressive cognitions, behaviors, and aggression-related attitudes, as well as individual differences predicting aggressive behavior and attitudes toward violence.

Jude Bergkamp is core faculty at Antioch University Seattle and program chair of the doctoral program in Clinical Psychology. His courses and trainings focus on cultural competency, social privilege, and positionality. He was featured in the Race in America video series by the American Psychological Association and received the Distinguished

Psychologist of the Year Award from the Washington State Psychological Association for his advocacy work challenging current federal immigration policy of Operation Streamline. His research interests include a developmental perspective of social privilege awareness, integrating social privilege into clinical work, and clinical implications of immigration policy. His dissertation research explored effective curriculum components in multicultural education at the doctoral level.

Navjot Bhullar, PhD, is an associate professor of psychology at the University of New England, Australia. Her research focuses on examining a range of psychological, emotional, and environmental factors influencing mental health and well-being.

Robert S. Blumenfeld is an assistant professor at the California State Polytechnic University, Pomona and leads the Brain Networks Laboratory. His research focuses on understanding the functional and structural organization of the prefrontal cortex in healthy individuals and in neuropsychiatric disorders.

Robert F. Bornstein received his PhD in clinical psychology from the State University of New York at Buffalo in 1986 and is professor of psychology at Adelphi University. Dr. Bornstein wrote *The Dependent Personality* (Guilford, 1993), *The Dependent Patient: A Practitioner's Guide* (APA Books, 2005), and co-authored (with Mary A. Languirand) *Healthy Dependency* (Newmarket Press, 2003). Dr. Bornstein is a fellow of the American Psychological Association, Association for Psychological Science, and Society for Personality Assessment; his research has been funded by grants from the National Institute of Mental Health and the National Science Foundation. He received the Society for Personality Assessment's 1995, 1999, 2002, 2008, and 2012 awards for Distinguished Contributions to the Personality Assessment Literature, the Division 12/American Psychological Foundation 2005 Theodore Millon Award for Excellence in Personality Research, and the Division 12 Section IX (Assessment Psychology) 2016 Distinguished Contribution Award.

Aaron Bortz is a research assistant and undergraduate student at Queens College of the City University of New York. He has helped conduct studies related to attachment theory and schizoid personality construct validity. As an intern at the New York Psychotherapy and Counseling Center, his responsibilities have included leading group counseling sessions.

Richard E. Boyatzis is Distinguished University Professor and professor in the Departments of Organizational Behavior, Psychology, and Cognitive Science at Case Western Reserve University, and Horvitz Professor of Family Business and adjunct professor in People/Organizations at ESADE. He was ranked ninth most influential international thinker by *HR Magazine* in 2012 and 2014. He is the author of more than 200 articles on leadership, emotional intelligence, coaching, and neuroscience. His MOOC Inspiring Leadership Through Emotional Intelligence has over 1,000,000 enrolled from 215 countries. His nine books include: *The Competent Manager*, *Primal Leadership* with Goleman and McKee; and *Resonant Leadership* with McKee, and recently *Helping People Change* with Smith and Van Oosten.

Melanie L. Bozzay received her BS in psychology from George Mason University in 2011. She also received her MA in psychology in 2015 from the University of South Florida, and is currently a fourth-year doctoral student at its Clinical Psychology program studying under the mentorship of Dr. Edelyn Verona. Her research focuses on identifying risk

factors for suicide that may be modifiable for intervention efforts, particularly with regards to cognitive mechanisms that may reduce behavioral inhibition, and thereby contribute to heightened risk of suicidal behavior.

Laura S. Brown, PhD, ABPP, is a feminist therapist practicing in Seattle WA, and the author of 13 books in the areas of feminist therapy, culturally competent practice, and trauma. Her most recent books include *The Feminist Model of Psychotherapy Supervision*, a companion to the APA DVD of the same name, and *Not the Price of Admission: Healthy Relationships after Childhood Trauma*. She holds a black belt in aikido.

Thomas Michael Brunner, PhD, is president of Dr. Brunner and Associates, and a nationally recognized psychologist, consultant, and expert. He was senior and co-author with Dr. Charles Spielberger on the final state-trait measure, which has been adapted into 14 languages. Author of numerous scientific publications, he has received several awards including some from the Society for Personality Assessment. A speaker at national and regional conferences, he is regularly consulted in high-stakes forensic cases given his expertise in assessment and evidence-based treatment. Recently he co-authored a research-focused book chapter entitled *Anger Management in Adolescence* in the book *Translating Psychological Research into Practice*.

Nicole M. Cain (PhD, Pennsylvania State University) is an associate professor of clinical psychology at Rutgers University in the Graduate School of Applied and Professional Psychology. Her research focuses on understanding how personality pathology and interpersonal functioning impact diagnosis, psychotherapy process, and treatment outcome.

Alyson Burns-Glover (PhD, University of California, Davis, 1989) is a full professor of psychology at Pacific University Oregon. She is a member of Divisions 2 (Teaching of Psychology), 8 (Personality and Social Psychology), 9 (Society for the Psychological Study of Social Issues) and 45 (The Society for the Psychological Study of Culture, Ethnicity, and Race). She has served as an executive committee member for Division 45 and has co-authored several chapters in culture and gender, e.g. A. Burns-Glover and B. Kasibhatla (2013). *Tensions and Intersections: Motherhood, Work, and Sexuality: U.S. and India Contexts*. In D. Castañeda (Ed.). *The Essential Handbook of Women's Sexuality*. Westport, CT: Praeger Publishers.

James R. Camp is a fourth-year undergraduate student working toward a BS in psychology at Western Washington University. He currently works with Joseph E. Trimble on the research and development of leadership psychology with a focus on culture and politics.

Bernardo J. Carducci, PhD, was Professor Emeritus of Psychology and Director of the Shyness Research Institute (www.ius.edu/shyness) at Indiana University Southeast and a fellow of the American Psychological Association in Divisions 1: General Psychology, 2: Teaching of Psychology, 8: Personality and Social Psychology, and 52: International Psychology. He was the author of *The Psychology of Personality: Viewpoints, Research, and Applications* (3rd ed., 2015, Wiley) and *Shyness: A Bold New Approach* (2000, HarperCollins) and other books related to shyness translated into multiple foreign languages.

Charles D. Cederberg received his MA in mental health counseling from Boston College and is currently completing a PhD in counseling psychology in the Department of Psychological and Quantitative Foundations at the University of Iowa. His areas of professional interest

include psychosocial well-being and talent development of high ability and twice exceptional youth; social class and classism; materialism, greed, and mental health; and personal branding in professional psychology.

Stan Charnofsky (EdD, University of Southern California, 1965) is a professor in the department of Educational Psychology and Counseling, at California State University, Northridge. He is coordinator of the Marriage and Family Therapy Masters' Degree program, was a past president of the Association for Humanistic Psychology (founded by Rogers, Maslow et al.) and is still a member of the AHP National Board. He is the author of two texts: *Educating the Powerless,* and *Therapy with Couples: A Humanistic Approach*. He has also published nonfiction books for the trade: *When Women Leave Men: How Men Feel, How Men Heal*, and *The Deceived Society*. In addition, he has published two novels: *Enemies* (2011) and *Ruthless* (2013).

Olivia Choy is an assistant professor in the Department of Psychology at Nanyang Technological University. She studies the etiology and treatment of criminal and antisocial behavior from a biopsychosocial perspective. Her current research covers the areas of psychophysiology, neuroimaging, neurostimulation, and nutrition with respect to antisocial behavior.

Alice Wenjui Cheng, PhD, is an assistant professor of psychology at the Bridgewater State University (BSU). She received her PhD in clinical psychology from the University of Rhode Island in 2011. She completed her APA-accredited internship at the Asian Pacific Family Center of Pacific Clinics in Los Angeles learning culturally adapted interventions for Asian Americans. Prior to joining BSU, Dr. Cheng was an assistant professor of psychology at the University of Hartford from Spring of 2012 to Spring of 2017. Her research interests are social-cultural contexts influencing health disparities among ethnic minorities, Asian American mental health, racial stereotypes, diagnostic bias, multicultural competency, and alcohol use disorders.

Jae Uk Chun is an associate professor of management at Korea University. He received his PhD in management from the State University of New York at Binghamton. His current research interests include leadership, character and leadership, mentoring relationships, feedback-seeking behavior, and multiple levels-of-analysis incorporation into theory development, measurement, and data analysis.

Sally H. Chung (PsyD, Azusa Pacific University, 2013) is in private practice in Bellevue, WA. She contributed to research on Future-Directed Therapy, a neuroscience-based cognitive group therapy for depression, which she has successfully conducted with community mental health and VA populations. She conducts psychotherapy with adults and couples in addition to providing psychological assessment. Her clinical interests include cultural identity, Asian American mental health, social media and mental health, and emotionally focused therapy.

Kevin Cokley, PhD, holds the Oscar and Ann Mauzy Regents Professorship for Educational Research and Development in the College of Education, where he is a professor of educational psychology and African and African diaspora studies at the University of Texas at Austin. He is a fellow of the UT System Academy of Distinguished Teachers and is the

director of the Institute for Urban Policy Research and Analysis. Dr. Cokley's research and teaching can be broadly categorized in the area of African American psychology. He is the past editor-in-chief of the *Journal of Black Psychology*. He was elected to fellow status in the American Psychological Association for his contributions to ethnic minority psychology and counseling psychology.

Donelda A. Cook, PhD, serves as the vice president for Student Development and Affiliate Faculty in the Pastoral Counseling Department at Loyola University Maryland. Her scholarly publications have focused on racial and cultural issues in counseling and psychotherapy and clinical supervision, as well as the integration of spirituality and psychology in psychotherapy with African Americans.

Andrés J. Consoli, PhD, is an associate professor in the Department of Counseling, Clinical, and School Psychology, University of California, Santa Barbara (2013–), distinguished visiting professor of psychology, Universidad del Valle, Guatemala (2004–); professor and associate chair, Department of Counseling, San Francisco State University (1996–2013). He is a recipient of the Interamerican Psychologist Award for distinguished contributions to the advancement of psychology in the Americas (2015), co-editor of the *Comprehensive Textbook of Psychotherapy: Theory and Practice* (2017), co-author of *CBT Strategies for Anxious and Depressed Children and Adolescents: A Clinician's Toolkit* (2017) and of "Integration in psychotherapy: Reasons and challenges" (*American Psychologist*, 2016).

Marina L. Costanzo holds a master's degree in clinical psychology from the University of Colorado and is currently a doctoral student in clinical psychology at the University of Montana. Her research is focused on historically under-researched and underserved populations including gender and sexual minorities. She is especially interested in support seeking and the effects of trauma and sexualized violence.

Mark A. Costanzo is professor and chair of Psychology at Claremont McKenna College. He has published research on a variety of law-related topics including police interrogations, false confessions, jury decision-making, sexual harassment, attorney argumentation, alternative dispute resolution, and the death penalty. Professor Costanzo is author of *Forensic and Legal Psychology* (with Dan Krauss), *Psychology Applied to Law*, and *Just Revenge: Costs and Consequences of the Death Penalty*. He has served as a consultant or expert witness for more than 200 criminal cases involving coerced and potentially false confessions.

Richard A. Currie is a graduate student in the Industrial/Organizational Psychology doctoral program at the University of Central Florida. He received his BA in psychology from the University of Missouri–Saint Louis. His primary research interests include intraorganizational competition, organizational climate, applicant reactions to employee recruitment and selection, and leadership.

Alv A. Dahl (MD 1969, PhD 1987 University of Oslo, Norway) was professor of psychiatry at the University of Oslo 1992 to 2003, and from 2003 to 2014 senior research advisor in psycho-oncology at Oslo University Hospital, the Norwegian Radium Hospital. His research interests concern personality and personality disorders as well as cancer survivorship with a special interest in work ability. He has written several textbooks in

Norwegian on topics like social anxiety, delusions, and psycho-oncology, and he is the editor of textbooks on psychiatry and psychosomatics.

Amber L. Davidson is a second-year doctoral student at the University of North Carolina at Charlotte. Her research interests include exploring how situational context influences the expression of personality, how emotions relate to workplace outcomes, and exploring within-person variability in behavior.

Catherine S. Daus is a professor of psychology at Southern Illinois University–Edwardsville with research interests in emotions, stress and coping, workplace wellness and family-friendly initiatives. Dr. Daus is an active invited contributor on emotional intelligence and emotional labor scholarly presentations and publications.

Erika S. DeJonghe, PhD, is a licensed clinical psychologist and an associate professor in the Department of Psychology and Sociology at California State Polytechnic University, Pomona. She received her doctorate in clinical psychology from Michigan State University in 2007. Dr. DeJonghe has two primary areas of scholarly focus. The first is in the area of violence against women, with a specific emphasis on intimate partner violence (e.g. DeJonghe, 2015). Recently, Dr. DeJonghe has developed a second line of research related to the experiences of women who are underrepresented in their academic disciplines (e.g. DeJonghe, Hacker, & Nemiro, 2015).

Kelly Donohue is a Psychologist for The Division of Developmental Disabilities for the State of Arizona and is part-time faculty for The College of Education at Northern Arizona University. She is board certified by the American Board of Professional Psychology in the specialty area of Administration in Counseling Psychology. She has presented both regional and national conferences and is the co-author of several peer reviewed articles. Current research interests include evidence based practices for co-occurring developmental disabilities and serious mental illnesses, integrative care and wellness, and diversity.

Ziya Ete is a doctoral student of management and organization at Drexel University. He received his MBA degree from the Pennsylvania State University, Great Valley School of Graduate Professional Studies. His major research interests are leadership development, character strengths and virtues, and diversity leadership.

Robert D. Enright is a professor in the Department of Educational Psychology at the University of Wisconsin–Madison and a licensed psychologist. He is a founding board member of the International Forgiveness Institute, Inc. in Madison. His research centers on the effectiveness of forgiveness therapy with adults and forgiveness education with children. He is the author of *Forgiveness Therapy* with Dr. Richard Fitzgibbons (2015, APA Books), 8 *Keys to Forgiveness* (2015, Norton). He is featured in the video for psychotherapists, Forgiveness therapy in practice (2016, APA Psychotherapy Videos), Washington, DC: American Psychological Association.

Nurcan Ensari is a professor at the Organizational Psychology Programs at Alliant International University. She is a social and organizational psychologist who teaches and conducts research in the area of intergroup relations, leadership and culture. She conducts multicultural research with international collaborators from England, India, Turkey, Greece and Hong Kong. She is also an ad hoc reviewer and editor for several journals, and

a recipient of a number of academic awards. Dr. Ensari holds an MA and a PhD in social psychology from the University of Southern California, an MA in social psychology and a BS in mathematics from Bogazici University in Istanbul, Turkey.

Katja Ermann is a doctoral student at Antioch University Seattle and a therapist at Ryther Child Center in Seattle, WA. Her research interests include child behavioral issues and parental support. Her dissertation explores the experience of mothers raising physically abusive children.

J. Paul Fedoroff, MD, is the director of the Sexual Behaviours Clinic (SBC) in the Royal's Integrated Forensic program. Under his leadership, the SBC was awarded the prestigious American Psychiatric Association Gold Award for the best outpatient clinical research program in 2015. Dr. Fedoroff is a full professor of psychiatry in the Faculty of Medicine with cross appointments in the faculty of Law and the Department of Criminology at the University of Ottawa. He is also a senior researcher with the Royal's Institute of Mental Health Research. He has been president of the International Academy of Sex Research and of the Canadian Academy of Psychiatry and the Law.

Héctor Fernández-Álvarez, PhD, founding member and honorary president of the Aiglé Foundation, a nongovernmental organization (NGO) that focuses on the professional development of mental health practitioners and the delivery of clinical and community services. He is a recipient of the Sigmund Freud award from the city of Vienna (2002), the senior career award from the International Society for Psychotherapy Research (2013), and the Award for Distinguished Contributions to the International Advancement of Psychology from the APA (2016). He is the author of *Fundamentals of an Integrated Model of Psychotherapy* (Fernández-Álvarez, 1992/2001), co-author of *Personality Disorders* (Belloch Fuster & Fernández-Álvarez, 2002) and *Treatise on Personality Disorders* (Belloch Fuster & Fernández-Álvarez, 2010).

Mercedes Fernández Oromendia, MA, is a doctoral candidate, Department of Counseling, Clinical, and School Psychology, University of California, Santa Barbara. She received the National Latina/o Psychology Association – Stephen C. Rose Scholarship for her commitment to research on mental health challenges facing college students of color. For her dissertation, she is developing and evaluating a tool to further supervisors' self-reflection and to identify commonalities and differences in style among supervisors.

Joseph R. Ferrari, PhD, is a St Vincent dePaul Distinguished Professor of Psychology at DePaul University, and a Permanent Deacon in the Catholic Church. The Rev. Dr. Ferrari is a social-personality psychologist and engages in applied social-community psychology research, with over 400 scholarly publications. He is editor of the *Journal of Prevention and Intervention in the Community* (Taylor & Francis, Publisher). He is a fellow in six professional organizations and received the 2016 APA/Italian American Distinguished Psychologist award.

Ian C. Fischer is a graduate student in the clinical psychology doctoral program at Indiana University–Purdue University Indianapolis. His research interests include hope and meaning in life. Of particular interest is how people deal with extraordinary life stressors that make salient existential issues of loss and limitation.

Alexis T. Franzese (PhD, Duke University, 2007 (sociology), 2011 (psychology)) is an associate professor of Sociology at Elon University. Her research is at the intersection of medical sociology and social psychology and addresses issues of self and identity, and the mental health consequences of inauthenticity. Her publications appear in journals including *Personality and Individual Differences*, *Sociology Compass, Aging and Mental Health,* and in other journals. She has contributed to edited volumes, including *The Handbook of Social Psychology, Authenticity in Culture, Self and Society and Others.*

Howard S. Friedman is distinguished professor at the University of California, Riverside. For his work on "changing how we think about the nature of health," he received the James McKeen Cattell Award from the Association for Psychological Science (APS), a top career award for applied scientific research. His research on disease-prone and self-healing personalities (terms he coined) led to the Outstanding Contributions to Health Psychology senior award from the American Psychological Association. His book, *The Longevity Project*, summarizes his 25-year scientific study of the pathways to health and long life. Over 100 of his scientific publications are regularly cited.

Y. Evie Garcia is an associate professor and doctoral training director of the PhD Counseling/School Psychology program at Northern Arizona University. She is President-elect of the American Psychological Association's Division 45: Society for the Psychological Study of Culture, Ethnicity, and Race (2020), President-elect of the Council of Counseling Psychology Training Programs (2021), and Past-president of the National Latinx Psychological Association (2017). She is co-editor of the Psychology of Race and Ethnicity book series, the three-volume book set, The Psychology of Inequity (2021 Praeger), and Emotions, Technology, and Health (2016, Elsevier). Current research interests include health disparities, diversity, and cultural aspects of leadership in psychology.

Luz M. Garcini, PhD, MPH, is an assistant professor at the Center for Research to Advance Community Health (ReACH) at the University of Texas Health Science Center at San Antonio. Dr. Garcini specializes in the study of health and well-being among marginalized immigrants, particularly those who are undocumented. Dr. Garcini has over 30 publications and multiple national and international presentations. Dr. Garcini is the author of a chapter addressing cultural concerns in the assessment of diverse populations in the book titled *Biopsychosocial Assessment in Clinical Health Psychology: A Handbook.*

Robert J. Gatchel is a diplomate of the American Board of Professional Psychology (ABPP) and a distinguished professor of the Department of Psychology and the director of the Center of Excellence for the Study of Health and Chronic Illnesses at the University of Texas at Arlington. Based on his extensive evidence-based clinical research in the area of pain, he has received numerous national and international awards and honors associated with his research, such as the *Wilber Fordyce Clinical Investigator Award* from the American Pain Society and, most recently, the 2017 American Psychological Foundation's *Gold Medal Award for Life Achievement in the Application of Psychology*.

Casey Giordano is a doctoral student in the Industrial/Organizational Psychology program at the University of Minnesota studying under Dr. Deniz S. Ones. He studies counterproductive work behaviors, individual differences, meta-analysis, and research methodology

with a quantitative bent. His work has been presented at international conferences and he has applied it to nonprofit and municipal organizations. He is a member of SIOP, Academy of Management, and EAWOP.

Joseph Glicksohn is a professor in the Department of Criminology, and in the Gonda Multidisciplinary Brain Research Center, at Bar-Ilan University, Israel. His areas of research include the study of sensation-seeking, the relationship between impulsivity and time perception, and electrophysiological and neuropsychological correlates of personality traits. He has recently published an article with Marvin Zuckerman on Personality and Individual Differences, looking at Hans Eysenck's personality model and the constructs of sensation-seeking and impulsivity. Another recent article (with Revital Naor-Ziv) was published in the *International Journal of Personality Psychology*, presenting a personality profile of pilots.

Cherie S. Y. Goh graduated from the National University of Singapore with a bachelor of social sciences in psychology and is currently a psychologist with the Home Team Behavioural Sciences Centre. She is attached to the Operations and Leadership Psychology Branch and is involved in leadership research and training of law enforcement and security officers, as well as the assessment and selection of high potential officers within the Ministry of Home Affairs.

Michael Goh is professor of comparative and international development education at the University of Minnesota and is affiliated with the university's Interdisciplinary Center for the Study of Global Change. Goh is also associate vice provost for equity and diversity and directs the Institute for Diversity, Equity, and Advocacy whose mission is to support a diverse and interdisciplinary community of scholars who produce scholarship on equity and diversity issues. Goh studies the role of intercultural competence in teaching and counseling and in 2012, published "Teaching with cultural intelligence: Developing multi-culturally educated and globally engaged citizens" in the *Asia Pacific Journal of Education*.

Sharon G. Goto is a professor of psychology and Asian American studies at Pomona College. Her research focuses on cultural values of individualism and collectivism, bicultural acculturative and cognitive strategies, and Asian Americans within organizations. She is the author of several articles, most recently regarding the influence of cultural values on analytic and holistic processing using various electrophysiological measures. She was a student of Harry C. Triandis at the University of Illinois, Urbana–Champaign.

Mark Hallahan is an associate professor of psychology at the College of the Holy Cross. He is an associate editor of the Personality and Social Psychology section of the journal *Frontiers in Psychology* and previously was a consulting editor for the *Journal of Personality and Social Psychology*. His research interests include attribution theory, nonverbal behavior and communication, and judgment and decision-making.

Jo-Ida C. Hansen is professor emerita of psychology and director of the Center for Interest Measurement Research at the University of Minnesota. Her research focuses on vocational psychology and career development and more specifically on the assessment of vocational and leisure interests.
Publications include "Career Counseling with Adults," *Oxford Handbook of Treatment Processes and Outcomes,* "Vocational and Leisure Interests: A Profile-level Approach to

Examining Interests" with M. E. Leuty and S. Z. Speaks, *Journal of Career Assessment,* and "Teasing Apart the Relations Between Age, Birth Cohort, and Vocational Interests" with M. E. Leuty, *Journal of Counseling Psychology*. Dr. Hansen co-edited the *Oxford Handbook of Counseling Psychology* with E. Altmaier.

Amber Haque, PhD is Professor of Clinical Psychology at the Doha Institute for Graduate Studies. Previously, he was Professor of Clinical Psychology at UAE University in Al Ain, UAE, and prior to that, he was Associate Professor and Head of Department of Psychology at International Islamic University Malaysia. Dr. Haque earned his Ph.D. in Psychology from Western Michigan University and a Master's in Clinical Psychology from Eastern Michigan University. He also taught part-time at the National University of Malaysia and the International University of Sarajevo, Bosnia. He worked as a psychologist for various mental health institutions in Michigan for over 12 years, published in the areas of mental health and indigenous psychology, edited six books, served as a board member for four, and reviewer for almost 40 international peer-reviewed journals.

Peter D. Harms is the Morrissette Faculty Fellow in Leadership and Ethics for the department of Management at the University of Alabama and a fellow of the Society for Industrial and Organizational Psychology. He received his PhD from the University of Illinois. His research interests include the assessment and development of personality, psychological well-being, and leadership.

Dietlinde Heilmayr is an assistant professor of psychology at Moravian College. Her research focuses on understanding how, when, and why holistic interventions such as community gardening improve health behaviors, social relationships, and environmental stewardship, thereby nudging individuals onto healthy lifespan trajectories.

Eric D. Heggestad is a professor of psychology and organizational science at the University of North Carolina at Charlotte. He is a fellow of the Society of Industrial and Organizational Psychology and is currently serving as associate editor for the *Journal of Business and Psychology*. His primary research interests involve issues of talent acquisition and development in organizations, with a particular focus on the development and use of personality assessments within those contexts. He is also interested in issues of psychological measurement and data quality.

Scott Highhouse is a professor and Ohio Regents Eminent Scholar in the Department of Psychology, Bowling Green State University. Scott is the founding editor of the journal *Personnel Assessment and Decisions*. He has been named a fellow of the American Psychological Association, the Association for Psychological Science, and the Society for Industrial Organizational Psychology. Scott formerly worked in organizational development at Anheuser Busch Companies in St. Louis, MO. His primary areas of expertise are assessment/selection for employment, and human judgment/decision-making. His work has been featured in the *Washington Post*, *Wall Street Journal*, and *Chronicle for Higher Education*.

Jacob B. Hirsh (PhD, University of Toronto, 2010) is an associate professor of organizational behavior and human resource management at the University of Toronto. His research focuses on understanding the role of personality processes in the workplace, especially as they relate to creativity, self-regulation, decision-making, and motivation.

Stefan G. Hofmann, PhD, is a professor of psychology at the Department of Psychology at Boston University where he directs the Psychotherapy and Emotion Research Laboratory. He is also the editor-in-chief of *Cognitive Therapy and Research*, and the associate editor of *Journal of Consulting and Clinical Psychology*. He was the 2013–2014 president of Association for Behavioral and Cognitive Therapy and the 2014–2017 president of the International Association for Cognitive Psychotherapy. Dr. Hofmann's research focuses on the mechanism of treatment change, translating discoveries from neuroscience into clinical applications, emotions, and cultural expressions of psychopathology. He is currently the Principal Investigator of an NIH study examining yoga as a treatment for generalized anxiety disorder and an NIH study examining d-cycloserine to augment cognitive behavioral therapy for social anxiety disorder. He published more than 300 peer-reviewed journal articles and 15 books. He is the recipient of many awards, is a fellow of the American Psychological Association and the Association for Psychological Science.

Emily L. Hughes, DPhil, was awarded a doctorate from the University of Oxford, Department of Experimental Psychology in 2007. She has a degree in psychology, and a master's degree in occupational psychology. She is a member of the British Psychological Society, and a chartered occupational psychologist. An independent consultant and researcher, her interests are work-family conflict and work stress. Her most recent publication is N. Payne, G. Kinman. G., and E. Hughes, E. (2016) "Job demands and resources, recovery strategies and work-life outcomes in UK fire and rescue service operational staff" and gave a presentation at the European Academy of Occupational Health Psychology Conference.

Ryan Hulla is currently a Ph.D. student in experimental psychology and a graduate research assistant at the University of Texas at Arlington. He was the former coordinator of the Center of Healthy Living and Longevity at the University of Arlington for four years, where his research focus was on the biopsychosocial aspects of pain and fall-risk in older adults. His more recent research consists of migraine and possible migraine treatment methods, teamwork, and the impact of work-school conflicts on college student's health.

Hyisung C. Hwang is an adjunct faculty at San Francisco State University. Her research interests are in emotion, nonverbal behaviors, and culture. She has also co-authored numerous scientific articles and book chapters on nonverbal behavior, facial expressions, and culture.

Wei-Chin Hwang, PhD, is a professor of clinical psychology at Claremont McKenna College. He received his PhD from the Clinical Psychology program at UCLA and completed a postdoctoral fellowship at Harbor UCLA Medical Center. His research focuses on mental health disparities, treatment outcomes, cultural competency, and developing frameworks for culturally adapting treatments. He is a fellow and has received career awards from the Asian American Psychological Association, American Psychological Association Minority Fellowship program, and the Western Psychological Association. Dr. Hwang is a licensed clinical psychologist and has an independent clinical and consulting practice in Pasadena and Claremont, California.

Adrienne S. Juarascio is an assistant professor in the Department of Psychology, director of Practicum Training, and a licensed clinical psychologist. Adrienne's line of research is focused on the development of innovative treatments for eating disorders and obesity.

James M. Jones is Trustees Distinguished Emeritus Professor of psychological and brain sciences and director of the Center for the Study of Diversity at the Universality of Delaware. He published *Prejudice and Racism* in 1972, and a second edition in 1997. His most recent book, *The Psychology of Diversity: Beyond Prejudice and Racism,* with Jack Dovidio and Deborah Vietze, was published in 2014.

Robert B. Kaiser is an author, advisor, and authority on leadership. He has published many articles and five books, including *The Versatile Leader* (2006) and *Fear Your Strengths* (2013), as well as the patented assessment instrument, *The Leadership Versatility Index.* He is the current editor-in-chief of *Consulting Psychology Journal.* Robert's research and writing is based on his extensive experience as an executive coach, as a strategic talent management advisor to CEOs and HR leaders, and as an assessor of candidates for executive-level jobs. He has conducted assessments, including personality tests, of thousands of leaders from companies around the world.

E. Kevin Kelloway is the Canada Research Chair in Occupational Health Psychology and Professor of Psychology at St. Mary's University. His research focuses on organizational and occupational health psychology, including the study of occupational stress, safety, leadership, and well-being.

Majeed Khader is a senior consultant psychologist, the director of the Home Team Behavioral Sciences Centre in Ministry of Home Affairs, Singapore. He holds a master's degree in forensic psychology from Leicester University (UK) and a PhD in psychology, (specializing in crisis and personality) from Aberdeen University (UK). Dr. Majeed teaches forensic psychology at Nanyang Technological University and is presently the Asian director for the Society of Police and Criminal Psychology (USA). He has also overseen the development of psychological services in the areas of stress, resilience, personnel selection, leadership, profiling, and crisis psychology in law enforcement settings.

Yeun Joon Kim (PhD, University of Toronto, 2019) is a University Senior Lecturer in Organisational Behaviour at the University of Cambridge's Judge Business School. His research interests include creativity, organizational resources, and morality. He studies how the structure and availability of organizational resources – information, time, task materials, and budget – influence creativity in the workplace. Yeun Joon also studies the intersection of creativity and morality, examining the impacts of moral reasoning, prosociality, and ethical leadership on creative performance.

Laura A. King is a Curators' Distinguished Professor of Psychological Sciences at the University of Missouri, Columbia. She is a fellow of American Psychological Association in Division 8 as well as the Society for Personality and Social Psychology, the Association for Psychological Science, and the Society for Experimental Social Psychology. As past editor of the *Journal of Personality and Social Psychology*, she has published over 100 articles and chapters on well-being and meaning in life.

Nancy Kishino, OTR/L, CVE, is a licensed and registered occupational therapist and director and owner of the West Coast Spine Restoration Center and the West Coast Spine and Sports Therapy Center in Riverside, California. Nancy has specialized in the management of spinal dysfunction for over 34 years, and has worked for more than 37 years in the areas of

physical disability and psychosocial dysfunction. She is the recipient of the Volvo Award won by the PRIDE team in 1985 for outstanding research on back and neck injured patients.

Natasha Knack is a clinical forensic researcher at the Royal's Institute of Mental Health Research. Her work involves designing and conducting research studies for the Sexual Behaviours Clinic, specializing in sexual interests and behaviors, sexual offending, and forensic mental health. She has conducted more than 150 research interviews, and has spent over 2,000 hours helping to co-facilitate psychotherapy groups for people who have engaged in sexual offenses or have problematic sexual interests. Ms. Knack has presented extensively on the topic of sexual offending, specializing in treatment strategies and motivations for offending, at both national and international conferences, as well as to relevant community organizations.

Susan Krauss Whitbourne is a professor of psychology at the University of Massachusetts Amherst. Her area of research is psychosocial development in adulthood with a focus on identity. Most recently, she is examining the relationship between the trajectories that individual lives take in the areas of work and family, and how these patterns of change relate to quality of psychosocial functioning through a 50-year sequential study of over 500 adults across the decades from college through retirement. As well as being editor of the *Encyclopedia of Adult Development and Aging*, she has authored a number of monographs, texts, and edited volumes; she is currently co-authoring a text on lifespan developmental science.

Ankita Krishnan (PhD, Purdue University, 2019) is a postdoctoral fellow at the Austin Child Guidance Clinic in Austin, Texas. A committee chair with the Asian American Psychological Association, she also is an affiliate of the American Psychological Association's Society for the Psychological Study of Culture, Ethnicity, and Race (Division 45), the Society of Clinical Psychology (Division 12), and the Society of Clinical Child and Adolescent Psychology (Division 53). Her research and clinical interests center on autism spectrum disorders among Asian child and emerging adult populations, the intersectionality of culture of assessment and treatment of neurodevelopmental disorders and mental health, and mental health and adjustment problems precipitated by intercultural contact and transition.

Hana Kuwabara is a graduate student in clinical psychology at the University of Nevada, Las Vegas. Ms. Kuwabara received her Masters degree in Psychology at the University of North Carolina Wilmington. She has special interest in clinical neuropsychology.

Nathan R. Landers served as a research assistant in the Center for Healthy Living and Longevity at the University of Texas at Arlington and is currently attending the University of Northern Colorado's PhD Counseling Psychology program with a research and professional focus on the efficacy of integrative treatment models with LGBTQ+ populations.

Sara Langford, PhD, is an associate professor of psychology in the Psychology and Sociology Department at California State Polytechnic University, Pomona. She earned her PhD in industrial/organizational psychology from Central Michigan University in 2010. She pursues research interests related to leadership, influence, relationships, and teaching/education.

Martin J. La Roche, PhD, has been director of Psychology Training at the Martha Eliot Health Center (which is the oldest standing community health center in the United States) for the last 21 years and is an associate professor in Psychology at the Harvard Medical School/Boston Children's Hospital. Dr. La Roche specializes in the development of culturally competent psychotherapeutic services and has been the principal investigator on several research projects in which he is refining these strategies. Dr. La Roche has over 100 publications and presentations, and Sage recently published his newest book titled *Cultural Psychotherapy: Theory, Methods and Practice*.

John C. Linton, PhD, ABPP, is associate vice president for health sciences and dean, West Virginia University School of Medicine, Charleston, WV. His current interests include factors influencing quality in academic health centers. His recent publications are: K. B. Schmaling and J. C. Linton (2017) "Psychologists in academic health administration: A call to action and service," and J. C. Linton (2017) "Now is the time for psychology to support the transformation of academic health centers." Both in the *Journal of Clinical Psychology in Medical Settings*.

Lisa M. Larson is a full professor of psychology and serves as the faculty fellow for the Iowa State University ADVANCE program (www.provost.iastate.edu/isu-advance). She is a fellow of the American Psychological Association in Division 17 (Counseling Psychology). Dr. Larson's scholarship includes 63 publications, five book chapters, 81 national conference presentation, and four technical reports. She is a co-principal investigator on three interdisciplinary National Science Foundation grants. Her research interests include explaining well-being using self-determination theory; examining the social cognitive model of counselor training which she developed, and understanding the overlap of personality, vocational interest, and vocational self-efficacy.

Gregory J. Lengel (PhD, Oklahoma State University, 2016) is currently an assistant professor of psychology at Drake University in Des Moines, Iowa. His program of research primarily explores the application of dimensional trait models to personality pathology and maladaptive behaviors (e.g. nonsuicidal self-injury). He is also interested in examining the utility of personality traits in clinical assessment and treatment.

Paul B. Lester is an associate professor of Management at the Naval Postgraduate School's Graduate School of Defense Management. Previously, he was the founding director of the Research Facilitation Laboratory in Monterey, California and an officer in the US Army. He received his PhD from the University of Nebraska–Lincoln and his research interests include leadership, resilience, and psychological health.

Kenneth N. Levy (PhD, City University of New York, 2000) is an associate professor in the Department of Psychology at the Pennsylvania State University, where he directs the Director of the Laboratory for Personality, Psychopathology, and Psychotherapy Research (www.levylab.psych.psu.edu). He is a fellow of the American Psychological Association (APA) in Division 29 (Society for Psychotherapy). He has authored more than 150 scientific articles and chapters in the areas of borderline personality disorder and its treatment in top journals such as *The American Journal of Psychiatry*, *The Journal of Consulting and Clinical Psychology*, and *Psychological Science*. His work has been funded by the National Institute

of Mental Health and a number of foundations. He has been recognized by the Society for Psychotherapy Research and Division 29 of the APA with early career awards and by the North American Society for Study of Personality Disorders with a mid-career award.

Scott O. Lilienfeld is Samuel Candler Dobbs Professor of Psychology at Emory University, Georgia and visiting professor at the University of Melbourne in Australia. He received his bachelor's degree in psychology from Cornell University and his PhD in Psychology (Clinical) from the University of Minnesota. He completed his clinical internship at Western Psychiatric Institute and Clinics (University of Pittsburgh). Dr. Lilienfeld is editor of *Clinical Psychological Science*, associate editor of *Archives of Scientific Psychology*, and most recently past president of the *Society for a Science of Clinical Psychology*. His research interests include personality disorders, psychiatric classification, and scientific thinking in psychology.

Jennifer Lodi-Smith is an assistant professor of psychology at Canisius College. Her program of research uses mixed methods to understand developmental processes in the content and clarity of individual identity. Her work addresses individual differences in identity content in the form of personality traits and narrative identity alongside the metacognitive process of self-concept clarity. Specifically, she studies the patterns, mechanism, and outcomes involved in the development of personality traits, narrative identity, and self-concept clarity over time in neurotypical individuals and individuals with high-functioning autism spectrum disorder.

Patricia "Denise" Lopez is associate professor of Organizational Psychology at Alliant International University, Los Angeles, CA. She is also an organization development consultant and certified executive coach. Her teaching and research interests are in leadership, organizational change, employee engagement and cultural diversity. Dr. Lopez has taught in graduate psychology, business and executive education programs in the United States, Turkey, Austria and various Asian countries. She completed her MA and PhD in Organizational Psychology at Columbia University, New York, and her BA in Psychology at Ateneo de Manila University, Quezon City, the Philippines.

P. Priscilla Lui (PhD, Purdue University, 2016) is assistant professor of clinical psychology in the Department of Psychology at Southern Methodist University. Her research interests broadly cover ethnic minority and multicultural issues in clinical psychology. Her studies revolve around assessment and measurement of personality and psychopathology, personal and socio-cultural determinants of subjective well-being, nonspecific distress, and psychological maladjustment such as alcohol and substance use.

Steven Jay Lynn is distinguished professor of psychology (SUNY) at Binghamton University. He received his bachelor's degree in psychology from the University of Michigan and his PhD in psychology (clinical) from Indiana University. He is the editor of *Psychology of Consciousness*: *Theory, Research, and Practice*, and he is on the editorial board of ten other journals, including the *Journal of Abnormal Psychology*. He has written or edited more than 20 books, and he has published more than 360 articles and chapters on the topics of dissociation, trauma, hypnosis, fantasy, psychotherapy, and scientific thinking in psychology.
